Abstract

The rising popularity of deep neural networks (DNNs) in computer vision has raised concerns about their robustness in the real world. Recent works in this field have well-demonstrated the vulnerability of these networks to carefully crafted adversarial attacks which yield out-of-distribution (OOD) samples. Interestingly, the majority of the existing literature focuses on adversarial attacks crafted for the digital domain only. Physical adversarial attacks are easier to deploy in the real world and yield higher attack success than digital perturbations. The prime limitation of such a dearth of studies handling physical out-of-distribution images is the lack of benchmark datasets. To overcome this limitation, this research proposes a novel out-of-distribution dataset using adversarial patches of different variations to advance the robustness of deep networks against such stealthy out-of-distribution images. We have also conducted extensive experiments both under seen and unseen patch settings and observed that unseen adversarial patches are hard to defend. By conducting this study and delving into the complexities of defending against patch attacks, we believe it will serve as inspiration for future researchers to incorporate physical OOD attacks into their defense strategies.

1. Introduction

While CNNs show tremendous success, their vulnerability against out-of-distribution (OOD) samples is a major concern. One popular form of getting an out-of-distribution sample is the addition of an adversarial pattern whether it is an imperceptible perturbation or visible patches [8, 9, 20]. Adversarial attacks can be classified into three broad categories based on the amount of perturbation: (i) imperceptible adversarial perturbations [34], (ii) universal perturbations [27], and (iii) physical adversarial patches [13, 22]. While novel adversarial attacks ensure that the DNNs are secure from any possible vulnerability, the defense algo-

Figure 1. Distribution shift among different adversarial attacks. The first row is imperceptible adversarial perturbation noise, the second is the universal perturbation vectors, and the third is the physical adversarial attacks.

ritms tackling them independently might be a severe concern [1, 6, 7]. It is seen that both imperceptible and universal adversarial perturbations have limitations in their transferability and applicability to the physical world, especially when compared to adversarial patch attacks. However, despite the real-world effectiveness of adversarial patch attacks, the majority of adversarial defense algorithms primarily focus on countering imperceptible adversarial perturbations (disturbing a very small number of pixels to induce misclassification). *It leaves a gap in developing a true defense algorithm that can counter the wide variety of adversaries that exist in the real world.*

We assert that ignoring the impact of adversarial patch attacks can be dangerous, especially when aiming to deploy these state-of-the-art DNNs in the unconstrained physical world. Figure 1 shows the adversarial noises, which when incorporated into the images yield a broad spectrum of out-of-distribution examples. The reason is that imperceptible and universal perturbations do not occlude any re-

gion of the images; however, the adversarial patches can occlude a small or significant portion of an image, depending on its size. We want to mention that while several benchmark studies are proposed in the literature to tackle the issue of adversarial defense, no work has included adversarial patch attacks. For example, Hendrycks and Dietterich [21] showcase the impact of several common corruptions, such as Gaussian noise, blur, and fog on deep neural networks (DNNs), but no defense has been proposed in this study. Dong et al. [17] proposed a benchmark study to tackle only the imperceptible adversarial perturbations. Recently, Agarwal et al. [2, 4] have performed several benchmark studies to counter adversarial perturbations and common corruptions; however, still, the OOD examples obtained physical patches are missing from the literature. It is also to be noted that several defense works also exist that can effectively detect imperceptible adversarial attacks in several generalized settings such as unseen datasets, unseen perturbation, and unseen threat model [1, 5, 6]. The evaluation of these defenses for physical patch adversaries is still an open-research direction.

As discussed, no studies have benchmarked the defense against adversarial patch attacks; therefore, in this research, we have performed the study by creating patch attack datasets. The OOD patch detection is performed using several deep image classification networks, including the network architecture search (NAS) method [40] and the vision transformer [19]. Neural Architecture Search (NAS) automates the process of designing optimal neural network architectures. Instead of relying on manual design, NAS employs algorithms to search and discover architectures that maximize performance for specific tasks. On the other hand, Vision Transformers (ViTs) are a recent breakthrough in computer vision. ViTs adopt the Transformer architecture, originally designed for natural language processing, and apply it directly to images. The prime reason for conducting a benchmark study on adversarial patches can also be understood from the distribution shift among the attacks and out-of-distribution handling limitations of the DNNs. We assert that the presence of the dataset and benchmark evaluation can help advance the research in this direction and make comparisons with new novel algorithms. In brief, the contributions of this research are:

- A novel adversarial patch attack dataset has been developed. The dataset contains images of multiple variations of patches. The presence of different style patches will ensure that the defense algorithms are not biased;
- A benchmark evaluation has also been conducted. For that, several real-world evaluations and protocols are developed to handle seen patches and unseen patches. A defined protocol can help make fair comparisons in

Figure 2. Samples of ten adversarial patches (arranged in an order, i.e., patch 0 is top left and patch 9 is bottom right) along with their target labels that are used to generate the proposed OOD datasets.

future works, which is often missing in imperceptible adversarial detection literature.

2. Related Work

The adversarial attacks on DNNs using crafted imperceptible perturbations are first introduced by Szegedy et al. [34]. They found an imperceptible adversarial perturbation can help in generating effective out-of-distribution samples which can trigger the misclassification of a deep neural network. Since then numerous methods to generate imperceptible adversarial perturbations have been proposed [25]. Surprisingly, the attacks are effective in fooling the deep neural networks working in different domains such as image classification [12, 24], geoscience [10, 38], segmentation and autonomous driving [28, 30].

While these imperceptible perturbations are found effective in fooling deep neural networks and are applicable in various vision tasks, some limitations halt their deployment in the real world. A few such critical limitations are transferability to unseen deep neural networks [36] and ineffectiveness in the physical world. To tackle the limitations of imperceptible adversarial patterns, an “adversarial patch attack” is introduced which contains malicious information which is visible but can result in stealthy out-of-distribution images that have higher physical world practicality [35, 37]. Adversarial patch attack on image classifiers is first proposed by Brown et al. [11], presenting a universal and targeted attack on real-world physical object detectors. Another approach to reducing the suspiciousness of adversarial patches to human eyes involved the creation of an adversarial QR patch [14]. Similar to the digital adversarial perturbations, adversarial patch-enhanced out-of-distribution images are effective in several domains such as point clouds [18], biometrics recognition [23, 33], and traffic sign recognition [39]. From the above review, it is observed that several adversarial patch generation algorithms have been proposed; however, one prime limitation of the literature is the inexistence of a benchmark out-of-distribution image dataset containing adversarial patch examples. The limita-

Figure 3. Samples of the different OOD adversarial patch images developed as part of our dataset. It can be seen that these patches can be blended with the image content and hence increase the complexity of its detection, especially when the detection network has not seen them in the training.

tion impacts the development of defense algorithms that can protect the integrity of deep networks against stealthy out-of-distribution adversarial patch images. We assert that this research is a first step towards that goal which presents a benchmark study in defending deep neural networks from out-of-distribution physical world adversaries.

3. Proposed Out-of-Distribution Dataset

Given the limited research in the area of detecting physical out-of-distribution images consisting of adversarial patches, this study aims to address the gap by introducing two novel adversarial patch datasets. These datasets have been curated using images of well-known datasets, namely ImageNet [16] and COCO (Common Objects in Context) [26]. We have used 2000 randomly selected images from the ImageNet dataset and treated them as the real subset of the proposed dataset. For the patched subset, on another 2000 randomly selected real images, ten different adversarial patches [29] as shown in Figure 2 are applied. Each of these patches is designed to be targeted toward a specific class, resulting in a diverse range of target classes for misclassification. Hence these patches not only have variations in texture and style but can also misclassify the images into different categories. *‘Thus, we have generated a large-scale adversarial patch dataset containing 20,000 patched images along with additional 2000 real images using the subset of ImageNet’.*

To extensively benchmark and understand the robustness of adversarial patch OOD examples detection, we have also utilized the COCO dataset. Similar to ImageNet, 4000 images are randomly selected from the dataset, out of which 2000 images are kept as real images, and on the remaining 2000 images each of the adversarial patches has been applied. **In total, the proposed dataset contains 40,000 (20,000 of ImageNet and 20,000 of COCO) adversarial patched images, and 4,000 real images.** Figure 3

Figure 4. Schematic diagram of the adversarial patch detection network.

shows some of the samples from the proposed dataset reflecting the challenge in detecting the adversarial attack not only due to *significant style change of the patches but also their blending nature with the complex image regions.*

4. Benchmarking Adversarial Patch Detection Results and Analysis

Architecture and Experiments: This research aims to overcome the limitation of the existing adversarial defense literature and benchmark state-of-the-art (SOTA) image classifiers for physical OOD examples detection. Henceforth, we have used several CNN-based architectures and vision transformers which varied in terms of basic architecture, the number of layers, the connection between layers, and their formation. The selected classifiers are as follows: XceptionNet [15], MobileNetv2 [31], NASMobileNet [40], VGG16 [32], and Vision Transformer [19]. The reason for using these architectures is that they are heavily popular for image classification. Further, NAS-style architectures and ViTs have not been explored comprehensively for adversarial patch detection. Therefore, benchmarking their robustness can pave the way to incorporate the adversarial nature of the images while crafting network architecture. Figure 4 shows the schematic diagram of the physical out-of-distribution adversarial patch detection framework.

These networks are fine-tuned by keeping approximately 60 percent of the network pre-trained on ImageNet and training the rest 40 percent of the network using the ImageNet patch subset. On top of that, two dense layers are added to extract features along with the classification layer to perform binary classification (real vs. patch). We split the ImageNet patch OOD subset into train and test sets in the ratio of 3:2 and trained all the models using the training set. Thus, each model has been trained on 1200 patched images of one patch class at a time and 1200 real images. In total, we have trained five different models on each of the ten patches and then tested each of these models on seen and unseen real and patch images of the ImageNet (seen OOD dataset) and COCO (unseen OOD dataset).

Results and Analysis: As described above, we have performed a comprehensive set of experiments in seen patches and unseen patches settings to effectively evaluate the per-

Table 1. Adversarial patch detection accuracy of the different architectures on ImageNet subset. The results are reported in terms of mean and standard deviation (SD), where the trained on one patch is tested on all the patches. Here X, NAS, and M represent Xception, NASNet, and MobileNet, respectively. The best mean and SD value is highlighted and underlined across each network, respectively.

formance and robustness of the image classifiers for adversarial patch detection. The analysis of the experiments can be broadly performed based on the following factors: (i) robustness of the classification model and (ii) effectiveness of the training patch. The brief experimental results on ImageNet and COCO datasets in terms of average classification accuracy are given in Tables 1 and 2, respectively. It can be seen that the ViT model which is pre-trained on the large-scale dataset, is shown state-of-the-art performance for OOD examples detection. Interestingly, the VGG model shows comparable performance to ViT and is not pre-trained on large-scale datasets on which ViT is trained. On the other other hand, the NASMobileNet architecture shows the lowest OOD examples detection performance on both datasets. However, it is to be noted that the standard deviation of the performance of NASNet is the lowest among all the networks. From the results of both datasets, it is interesting to note that, for pre-defined network structures such as VGG and XceptionNet, patch 4 is found the most robust (unseen dataset and patch) architecture to detect OOD adversaries. Whereas ViT found patch-2 as the most effective and NASMobileNet found patch 7 as the most effective patch detector both under seen and unseen patch evaluation settings. Out of all the networks, Mo-

bileNet archived the highest accuracy when trained on patch 0 (Table 1) and patch 4 under unseen dataset setting (Table 2). However, the performance of MobileNet is inconsistent when different types of patches are used for training. It can also be analyzed from the heatmaps (Figure 5) where the MobileNet shows the best performance majority of the time when it is trained on the individual patches of both datasets.

Tables 3 and 4 provide the detailed performance of each network and how they have performed when they are trained on a specific patch and evaluated on the same and unseen patches. Here the analysis can be broken into generalized conditions: (i) seen patch detection on the same training-testing dataset and (ii) unseen patch detection on the same training-testing dataset. The diagonal elements of these tables represent the performance of the models on seen patches. As expected, the models perform best on the seen patches but are found vulnerable against unseen patches. Out of all the networks, ViT and VGG show high performance in detecting the patches which are seen at the time of training. As mentioned that the biggest real-world challenge for a defense algorithm is that at the time of testing, out-of-distribution attack (patch) images come for classification. Henceforth, the desired goal for an ideal defense algorithm is the robustness in handling these unseen attack

Table 3. Adversarial patch detection accuracy of the different architectures on **ImageNet** subset under seen and unseen patch detection scenarios. Seen settings results are highlighted and the best unseen-test patch performance is underlined.

Table 4. Adversarial patch detection accuracy on **COCO** subset under seen and unseen patch detection scenarios. Here the evaluation has been performed under ‘duly’ generalized settings, including where the dataset and patches for testing are also unknown to the adversarial detection training models. Seen settings results are highlighted and the best unseen-test patch performance is underlined.

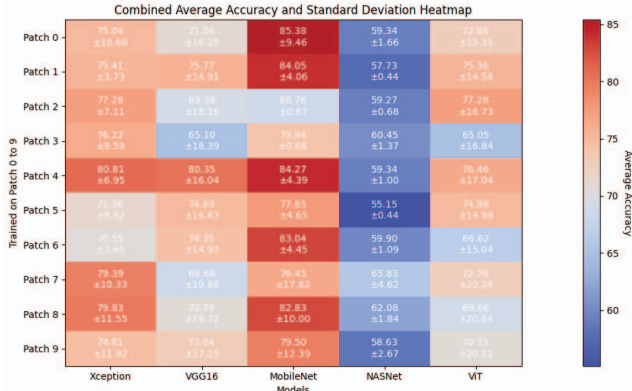

Figure 5. Average and standard deviation performance of each model when trained on individual adversarial patches of datasets (ImageNet: top and COCO: bottom). Here the average accuracies are from red to blue where red being the high effectiveness of a model and blue representing the ineffectiveness of a model in detecting patches.

distributions. *In such real-world defense challenges, the MobileNet outperforms the other networks by a significant margin.* In terms of the performance of individual patches, it is observed that when the models are trained on patches 0 and 3, they are found most resilient in handling patch 2. Similarly, when the models are trained on patch 9, they are not only effective in handling patch 9 but can also detect patch 8. Patch 6 trained models are effective in handling patch 1.

Figure 6 and Figure 7 illustrates the robustness of each classifier when trained and tested on both seen and unseen attack patches of ImageNet and COCO dataset, respectively. The classifiers observed significant drops in performance when attempting to classify adversarial patches that were not seen during training. This decline in performance can be attributed to two main factors: first, the shift in style texture distribution among the patches, and second, the challenging blending of these patches with complex image regions.

An interesting finding is that if we only consider the percentage drop in accuracy, we can see that NASMobileNet

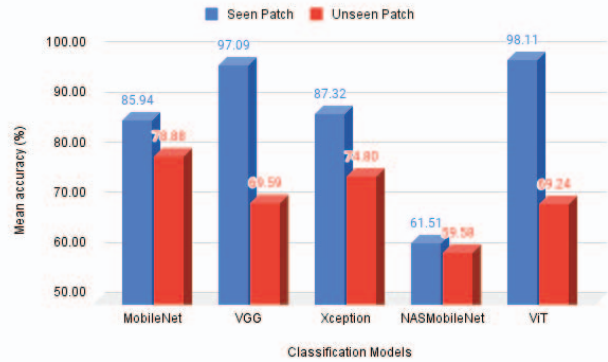

Figure 6. Average adversarial patch attack detection performance on the ImageNet subset under seen and unseen patches evaluation setting. The results reflect that when unseen patches come for classification, the performance of the networks drops drastically.

Figure 7. Average adversarial patch attack detection performance on the COCO subset under seen and unseen patches evaluation setting. The results reflect that when unseen patches come for classification, the performance of the networks drops drastically.

demonstrates the highest level of generalizability across different patches. Although, it is also found to have the lowest network capacity, referring to its performance in seen patches training and testing conditions. For instance, NASMobileNet’s performance drops by 3.1% in the unseen patches setting compared to the seen patches setting. Nevertheless, it still lags behind other architectures by at least 28.4% in the seen evaluation setting. Despite these challenges, NASMobileNet presents promising prospects for the development of a robust adversarial patch detection classifier. This could be achieved by intelligently incorporating adversarial patch information during the architecture search process, thereby enhancing its ability to detect attacks effectively.

5. Conclusion

The vulnerability of different convolutional neural networks, including vision transformers [3], to adversarial attacks is a significant concern when considering their real-world deployment. Out of several adversarial perturbations,

an adversarial patch is one of the most complex and highly effective physical world attacks, yet there has been limited focus on developing defenses against it. To address this gap, we have created a comprehensive dataset containing 44,000 images, comprising both real and adversarially patched examples. These adversarial patch examples can be seen as out-of-distribution (OOD) examples due to having significantly different distribution than the images on which the networks are trained. Using this dataset, we conducted an extensive benchmark study to understand whether the current image classification models are sufficient enough to detect these OOD samples. Our experimental analysis revealed that the image classifiers are effective in detecting the adversarial patch attack; however, the catch they must be seen during the training of the detector. The challenge is exacerbated when dealing with images from out-of-distribution settings, meaning datasets that were not seen or considered during training, testing, and evaluation. In the future, we aim to expand the dataset and develop a sophisticated and robust architecture for detecting out-of-distribution adversaries.
