Abstract

We present a deep learning solution for estimating the incident illumination at any 3D location within a scene from an input narrow-baseline stereo image pair. Previous approaches for predicting global illumination from images either predict just a single illumination for the entire scene, or separately estimate the illumination at each 3D location without enforcing that the predictions are consistent with the same 3D scene. Instead, we propose a deep learning model that estimates a 3D volumetric RGBα model of a scene, including content outside the observed field of view, and then uses standard volume rendering to estimate the incident illumination at any 3D location within that volume. Our model is trained without any ground truth 3D data and only requires a held-out perspective view near the input stereo pair and a spherical panorama taken within each scene as supervision, as opposed to prior methods for spatially-varying lighting estimation, which require ground truth scene geometry for training. We demonstrate that our method can predict consistent spatially-varying lighting that is convincing enough to plausibly relight and insert highly specular virtual objects into real images.

1. Introduction

Rendering virtual objects into photographs of real scenes is a common task in mixed reality and image editing. Convincingly inserting such objects requires estimating both the geometry of the scene (so that inserted objects are correctly occluded by real scene content) as well as the incident illumination at points on each object’s surface (so that inserted objects appear to be lit by the surrounding environment). The difficulty of this task is exacerbated by the fact that incident illumination can vary significantly across different locations within a scene, especially indoors, due to lights close to the inserted objects, shadows cast by scene geometry, and global illumination effects from nearby scene con-

* Authors contributed equally to this work.

Figure 1: Our method predicts environment map lighting at any location in a 3D scene from a narrow-baseline stereo pair of images. We use this to convincingly insert specular objects into real photographs with spatially-coherent lighting that varies smoothly in 3D. Below, we isolate the relit objects to better visualize our estimated illumination. Notice how each inserted object contains different specular highlights and reflected colors corresponding to its 3D location, such as the light reflected on the cow’s head and the corner of the table visible on the teapot.
We specifically use a narrow-baseline stereo pair as input because: 1) multi-camera systems are ubiquitous in modern smartphones, 2) stereo enables us to estimate the high fidelity geometry required for simulating spatially-varying lighting effects due to observed scene content, and 3) we can leverage recent progress in using narrow-baseline stereo images to predict 3D scene representations for view synthesis. To address this shortcoming, many subsequent methods [15, 21, 22, 32] have demonstrated that machine learning techniques can be used to estimate an HDR environment map from a single low dynamic range (LDR) photograph. However, a single environment map is insufficient for compositing multiple, large, or moving virtual objects into a captured scene, especially in indoor settings where light sources and other scene content may be close to the object insertion locations. To address this shortcoming, many works predict spatially-varying lighting from images by estimating a separate environment map for each pixel in the input image. Such approaches include algorithms designed specifically for spatially-varying lighting estimation [14] as well as methods that address the more general inverse rendering problem of jointly estimating the spatially-varying lighting, scene materials, and geometry that together produce an observed image [26, 34]. However, these approaches do not ensure that the illuminations predicted at different spatial locations correspond to a single 3D scene,

We demonstrate that estimating spatially-varying global illumination as a persistent 3D function quantitatively and qualitatively outperforms prior approaches. Our spatially-coherent estimated lighting can simulate convincing global illumination effects for rendering specular virtual objects moving within scenes. We encourage readers to view animations of these results in our supplementary video.

2.1. Estimating lighting from images

Inferring the intrinsic properties of lighting, materials, and geometry that together form an image is a fundamental problem that has been studied in various forms throughout the history of computer vision [2, 16]. Below, we review relevant prior works that use images to estimate representations of lighting for relighting virtual objects.

Seminal work by Debevec [7] showed that virtual objects can be convincingly inserted into real photographs by rendering virtual object models with high dynamic range (HDR) environment maps captured with bracketed exposures of a chrome ball. Many subsequent methods [4, 13, 15, 21, 22, 32] have demonstrated that machine learning techniques can be used to estimate an HDR environment map from a single low dynamic range (LDR) photograph.

However, a single environment map is insufficient for compositing multiple, large, or moving virtual objects into a captured scene, especially in indoor settings where light sources and other scene content may be close to the object insertion locations. To address this shortcoming, many works predict spatially-varying lighting from images by estimating a separate environment map for each pixel in the input image. Such approaches include algorithms designed specifically for spatially-varying lighting estimation [14] as well as methods that address the more general inverse rendering problem of jointly estimating the spatially-varying lighting, scene materials, and geometry that together produce an observed image [26, 34]. However, these approaches do not ensure that the illuminations predicted at different spatial locations correspond to a single 3D scene,

We demonstrate that estimating spatially-varying global illumination as a persistent 3D function quantitatively and qualitatively outperforms prior approaches. Our spatially-coherent estimated lighting can simulate convincing global illumination effects for rendering specular virtual objects moving within scenes. We encourage readers to view animations of these results in our supplementary video.

2. Related Work

2.1. Estimating lighting from images

Inferring the intrinsic properties of lighting, materials, and geometry that together form an image is a fundamental problem that has been studied in various forms throughout the history of computer vision [2, 16]. Below, we review relevant prior works that use images to estimate representations of lighting for relighting virtual objects.

Seminal work by Debevec [7] showed that virtual objects can be convincingly inserted into real photographs by rendering virtual object models with high dynamic range (HDR) environment maps captured with bracketed exposures of a chrome ball. Many subsequent methods [4, 13, 15, 21, 22, 32] have demonstrated that machine learning techniques can be used to estimate an HDR environment map from a single low dynamic range (LDR) photograph. However, a single environment map is insufficient for compositing multiple, large, or moving virtual objects into a captured scene, especially in indoor settings where light sources and other scene content may be close to the object insertion locations. To address this shortcoming, many works predict spatially-varying lighting from images by estimating a separate environment map for each pixel in the input image. Such approaches include algorithms designed specifically for spatially-varying lighting estimation [14] as well as methods that address the more general inverse rendering problem of jointly estimating the spatially-varying lighting, scene materials, and geometry that together produce an observed image [26, 34]. However, these approaches do not ensure that the illuminations predicted at different spatial locations correspond to a single 3D scene,
and their approach of indexing lighting by image pixel coordinates cannot estimate lighting at locations other than points lying directly on visible scene surfaces. Karsch et al. [18] also address a similar inverse rendering problem, but instead estimate area lights in 3D by detecting visible light source locations and retrieving unobserved light sources from an annotated panorama database.

Our work is closely related to prior deep learning methods that estimate a portion of lighting in 3D. Neural Illumination [38] predicts the incident illumination at a location by first estimating per-pixel 3D geometry for the input image, reprojecting input image pixels into an environment map at the queried location, and finally using a 2D CNN to predict unobserved content in the resulting environment map. This strategy ensures spatial consistency for light emitted from scene points that are visible in the input image (for which a single persistent geometry estimate is used), but because the environment map is separately completed for each lighting location using a 2D CNN, the lighting from unobserved scene points is not spatially-coherent. Recent work by Gardner et al. [12] trains a deep network to estimate the positions, intensities, and colors of a fixed number of light sources in 3D, along with an ambient light color. This ensures spatially-coherent lighting, but is unable to simulate realistic global illumination effects or light source occlusions, which can be very significant in indoor scenes, and therefore has difficulty rendering realistic specular objects. Furthermore, both of these methods require ground truth scene depths for training while our method only requires perspective and spherical panorama images.

2.2. Predicting 3D scene representations

Our strategy of estimating consistent spatially-varying lighting by predicting and rendering from a 3D scene representation is inspired by recent successes in using 3D representations for the image-based rendering problem of predicting novel views of a scene. Shum and Kang [35] provide an excellent review of classic approaches, ranging from light field rendering methods [24] that do not use any scene geometry, to texture mapping methods [8, 33] that use a global scene mesh. A key lesson from early work on image-based rendering is that more knowledge of scene geometry reduces the number of sampled images required for rendering new views [3, 5]. Modern approaches to view synthesis follow this lesson, rendering novel views by predicting representations of 3D scene geometry from sparsely-sampled collections of images. In particular, many recent methods predict layered or volumetric 3D scene representations, which have a regular grid structure that is well-suited to CNN pipelines. This includes algorithms for synthesizing novel outwards-facing views of large scenes [11, 29, 39, 43] and inwards-facing views of objects [28, 37, 42].

We adopt the approach of Zhou et al. [43] for learning to predict a layered representation of observed scene content. Their algorithm trains a CNN to predict a set of fronto-parallel RGBα planes sampled evenly in disparity within the camera frustum. Training proceeds by minimizing the difference between renderings of their model and held-out novel views, thereby obviating the need for ground truth 3D supervision. This representation, which they call a multi-plane image (MPI), is closely related to representations used in volume rendering [9, 20, 23] and stereo matching [40]. Though this approach works well for view synthesis, it cannot be directly used for estimating spatially-varying lighting, as the majority of the illumination needed for relighting and compositing virtual objects often resides outside of the input image’s field of view. We address this shortcoming by extending these models to predict a multiscale volumetric representation that includes scene content outside the input image’s camera frustum, thereby allowing us to estimate incident illumination at any 3D location in the scene.

3. Multiscale Lighting Volume Prediction

Our goal is to take in a narrow-baseline pair of RGB images and associated camera poses, and output the incident illumination (represented as a spherical environment map) at any queried 3D location within the scene. Due to dataset limitations (see Sec. 5.2), we do not address LDR-to-HDR conversion and assume that the inputs are either HDR captures or that they can be converted to HDR by inverting a known tone mapping curve or by applying existing LDR-to-HDR conversion techniques [10].

We train a deep learning pipeline, visualized in Fig. 2, that regresses from the input image pair to a volumetric RGBα representation of the entire scene that includes areas outside of the reference camera frustum (we choose one of the two input images as the “reference” to be the center of our coordinate system), thereby allowing the illumination at any 3D location to be estimated by simply rendering the scene volume at that location. This representation enables us to reproduce effects such as: shadowing due to the occlusion of light sources by other scene content, realistic reflections on glossy and specular virtual objects, and color bleeding from the scene onto relit objects.

Naïvely representing an entire indoor scene as a dense high-resolution voxel grid is intractable due to memory constraints. Instead, we propose a multiscale volume representation designed to adequately sample the varying depth resolution provided by stereo matching, allocate sufficient resolution to areas where virtual objects would be inserted, and allocate lower resolution outside the observed field-of-view where scene content must be hallucinated. As shown in Fig. 2 our procedure for predicting this volume is: 1) A deep network predicts a layered representation of observed scene content from the input narrow-baseline stereo pair (Fig. 2a). 2) This layered representation is resampled onto a
multiscale lighting volume that preserves the observed content representation’s resolution (Fig. 2b). 3) Another deep network completes the multiscale lighting volume by hallucinating scene geometry and appearance outside the observed field of view (Fig. 2c). Once we generate a lighting volume for a scene, we can use classic volume rendering to estimate the incident illumination at any 3D location without requiring any network inference (Fig. 2d).

3.1. Observed content intermediate representation

We construct an intermediate representation of observed scene content as an MPI \( M \), which consists of a set of fronto-parallel RGB\( _\alpha \) planes within the frustum of a reference camera, as visualized in Fig. 3a. As in Zhou et al. [43], we select one of the input images as a reference view and construct a plane sweep volume (PSV) in this frame for both input images. We concatenate these two PSVs along the channel dimension, forming an input tensor for a 3D encoder-decoder CNN that outputs an MPI, as suggested by follow-up works on MPI prediction [29, 39].

3.2. Multiscale volume resampling

This MPI provides an estimation of geometry for regions of the scene observed in the two input images. However, inserting a relit virtual object into the scene also requires estimating geometry and appearance for unobserved areas behind and to the sides of the input cameras’ frustums, as visualized in Fig. 3, so our lighting representation must encompass this area. Furthermore, our volumetric lighting representation should allocate higher resolution to regions where we would insert objects in order to correctly render the larger movement of nearby content within environment maps as the queried location changes.

We design a multiscale volume lighting representation that encompasses both observed and unobserved regions, allocates finer resolution within the input field-of-view, and increases in resolution towards the front of the MPI frustum (which contains increasingly higher resolution estimated geometry from stereo matching). We initialize this multiscale volume by resampling the RGB\( _\alpha \) values from the MPI frustum onto a series of nested cubes \( V^o = \{V^o_1, \ldots, V^o_L\} \) encompassing the whole scene, using trilinear interpolation. From the coarsest to finest level, each cube \( V^o_\ell \) is half the spatial width of the previous level \( V^o_{\ell-1} \) while maintaining the same grid resolution of 64\(^3\). The largest, outermost cube \( V^o_1 \) is centered at the first input camera pose and is wide enough to contain the whole MPI volume. Each smaller nested cube is offset such that the input camera pose lies at the back face of the cube. See Fig. 4 for a visualization of the MPI sampling pattern and how we resample it onto the multiscale volume structure. We find that this multiscale sampling pattern works well in practice for rendering convincing near-field lighting effects caused by scene geometry at our chosen environment map resolution of 120 \( \times \) 240.

3.3. Multiscale volume completion

Now that we have a volumetric representation \( V^o = \{V^o_1, \ldots, V^o_L\} \) of the entire scene that has been populated with observed content, we use a deep network to hallucinate the geometry and appearance of the unobserved content. We denote this “completed” multiscale volume by \( V^c = \{V^c_1, \ldots, V^c_L\} \). We design a 3D CNN architecture that sequentially processes this multiscale volume from
the coarsest to the finest resolution, predicting a completed volume \( V_c^{\ell} \) at each resolution level. For each level, we first nearest-neighbor upsample the region of the previous coarser completed volume \( V_c^{\ell-1} \) that overlaps the current level \( V_c^{\ell} \) to \( 64^3 \) resolution. Then, we concatenate this to the current level’s resampled volume \( V_c^{\ell} \) along the channel dimension and use a 3D encoder-decoder CNN to predict the current level’s completed volume \( V_c^{\ell} \), with separate weights for each level. Figure 4 visualizes our coarse-to-fine network architecture. Please refer to our supplementary PDF for exact architecture specifications.

4. Illumination Rendering

Given our multiscale lighting volume \( V_c \), we estimate the illumination incident at any 3D location by using standard RGB\( \alpha \) volume rendering [23] to generate a spherical environment map at that point (visualized in Fig. 5). In order to get the value at a pixel \( p \) for an environment map located at location \( x \), we must:

1. Generate the ray \( r \) (in world coordinates) that originates at \( x \) and intersects pixel \( p \) on the sphere, and

2. Trace \( r \) through the volume \( V_c \), using alpha compositing to matte in the RGB\( \alpha \) values as it intersects voxels from farthest to nearest.

As we trace \( r \) through \( V_c \), we query the finest level defined at that location in space to ensure that predicted RGB\( \alpha \) values at coarser levels never override predictions at finer levels. This rendering procedure is very fast since it does not involve network inference and is trivially parallelizable on GPUs, allowing us to render environment maps from a predicted multiscale volume at 100 frames per second.

5. Training and Dataset

Our model is trained end-to-end: a stereo pair is provided as input, the model renders a held-out novel view (sampled close to the reference view) from the intermediate MPI and a held-out environment map (sampled within the scene in front of the reference camera) from the completed multiscale lighting volume, and we update the model parameters only using the gradient of losses based on these two supervision images. This is possible since all steps in our pipeline are differentiable, including the multiscale volume resampling and the environment map rendering. Therefore, we do not require ground-truth geometry or other labels, in contrast to prior works in spatially-varying lighting estimation which either require scene geometry as supervision [14, 26, 32, 38] or for creating training data [12].

5.1. Training loss

The loss we minimize during training is the sum of an image reconstruction loss for rendering a held-out perspective view from our predicted MPI, an image reconstruction loss for rendering an environment map from our completed multiscale lighting volume, and an adversarial loss on the rendered environment map to encourage plausible high frequency content. For our reconstruction loss, we use a perceptual loss \( L_{\text{vgg}} \) based on features from a pre-trained VGG-19 network [36], as done by Chen and Koltun [6]. For our adversarial loss, we follow recent work in conditional image generation [31, 41] and use a PatchGAN [17] discriminator \( D \) with spectral normalization [30] and a hinge adversarial loss [27]. We train all networks in our pipeline by alternating between minimizing the reconstruction and adversarial losses with respect to the MPI prediction and volume completion networks’ parameters:

\[ L_{\text{train}} = L_{\text{vgg}}(i_r, i_{gt}) + L_{\text{vgg}}(e_r, e_{gt}) - D(e_r), \] (1)

and minimizing the discriminator loss with respect to the discriminator network’s parameters:

\[ L_{\text{dis}} = \max(0, 1 - D(e_{gt})) + \max(0, 1 + D(e_r)), \] (2)

where \( i_r, i_{gt}, e_r, e_{gt} \) are the rendered and ground-truth perspective image and environment maps, respectively.

5.2. Dataset details

We train our model with photorealistic renderings of indoor scenes from the InteriorNet dataset [25]. We use 1634 of the provided camera sequences, each containing 1000 perspective projection images and 1000 spherical panorama images rendered along the same camera path. We reserve 10% of these sequences for our test set, and sample training examples from the remaining 90% of the sequences.

The images included in InteriorNet are not HDR, and unfortunately no equivalent dataset with HDR radiance values...
Currently, we assume that the InteriorNet images can be treated as linear radiance values by applying an inverse gamma curve \( x^\gamma \), with \( \gamma = 2.2 \).

To generate training examples from a sequence, we randomly sample three perspective projection images, evenly separated with a gap between 1 and 8 frames along the sequence’s camera path, and a single spherical panorama image within 40 frames of the central perspective projection frame. Two of the perspective projection images are randomly selected to be the input to our model, while the third perspective image and the spherical panorama image are used as supervision. We reject training examples where the camera is closer than 0.1m from the scene, examples where adjacent perspective cameras are separated by less than 0.05m, and examples where the average pixel brightness is lower than 0.1. Additionally, we reject examples where the spherical panorama camera does not move more than the median scene depth into the scene, relative to the central perspective projection camera, so that the environment map locations we use for supervision are representative of realistic object insertion locations.

### 5.3. Additional details

We implement our full training pipeline in TensorFlow [1] and train our model on a single NVIDIA Tesla V100 GPU using the Adam optimizer [19] with a batch size of 1. For more stable training, we first pre-train the MPI prediction network for 240k iterations, then train both the MPI prediction network and volume completion networks with just image reconstruction losses for 450k iterations, and finally add the adversarial losses and train both networks along with a discriminator for an additional 30k iterations. We use an Adam step size of \( 10^{-4} \) for the first two stages and \( 10^{-5} \) for the third stage.

### 6. Results

We validate the benefit of our algorithm by comparing our estimated environment maps to those of current state-of-the-art algorithms and ablated versions of our model. Please view our supplementary video for example results that demonstrate our method’s ability to estimate realistic and consistent spatially-varying lighting.

For quantitative comparisons (Table 1), we sample a test set of 4950 examples (using the same training example rejection criteria described above in Sec. 5.2) from our InteriorNet test set, which consists of 163 camera sequences that were held out during training. Each example consists of two input images and one ground truth environment map that represents the lighting at a random 3D location within the reference camera frustum. We select a subset of these examples to show comparisons of virtual object insertion results in Fig. 6 and show additional insertion results for our method on real photographs in Fig. 7.

### 6.1. Comparisons to baseline methods

We compare our method to trained models of DeepLight [22] and Garon et al. [14] (which both take a single image as input) provided by the authors, and to a generous re-implementation of Neural Illumination [38] that has access to ground-truth geometry, in order to provide a fair comparison against our method which requires stereo input. Note that all quantitative metrics are computed on LDR images, due to the limitations of the InteriorNet dataset.

DeepLight [22] takes in a single image and outputs one HDR lighting map for the entire scene. The training data used for supervision is a set of three light probes placed 60cm in front of the camera; thus, this location is where the predicted lighting should be most accurate. The lighting is output in the form of a \( 32 \times 32 \) HDR image of a mirror ball light probe. In order to compare these results with our method, we resample the mirror ball onto a higher resolution \( 120 \times 240 \) spherical environment map, rotated to match the orientation of the target environment map. Because DeepLight does not predict spatially varying lighting, it underperforms our method on our test set of environment maps at various locations within the scene (see Table 1). Qualitatively, the limitations of a single environment map are apparent in relighting results since inserted objects cannot be correctly relit as they are moved around the scene, as we show in our supplementary materials.

Garon et al. [14] predicts spatially-varying lighting from a single image. Given a particular pixel on an object surface, the method is supervised to match the lighting 10cm away from that surface in the normal direction. This allows for
some spatially-varying effects but heavily restricts the supported lighting locations. Additionally, this method predicts a low-dimensional representation of the environment map as 36 spherical harmonic coefficients for efficiency. Since our test set consists of higher resolution $120 \times 240$ environment maps sampled at locations that are not restricted to be near surfaces, this method performs significantly worse in our quantitative comparisons (see Table 1). Qualitatively, this lighting representation is sufficient for relighting diffuse objects, but its low resolution prevents it from plausibly relighting glossy and specular objects (see Fig. 6).

Neural Illumination [38] estimates lighting at any 3D scene point by first predicting a per-pixel geometry for a single input image, warping the input image with this geometry to render an incomplete environment map, using a 2D CNN to inpaint unobserved content, and finally using another 2D CNN to convert the environment map to HDR. We did not have access to the authors’ original implementation, so we implemented a generous baseline that uses the ground truth depth to warp the visible scene content into an incomplete spherical environment map, then uses a 2D CNN to complete the lighting map (see the supplementary PDF for additional details). Despite having access to the ground truth geometry for the observed portion of the scene, this method is not guaranteed to produce spatially-coherent lighting predictions for the unobserved regions of a given scene, because the 2D completion CNN is run independently at each queried location. In contrast, our single multiscale 3D representation of the entire scene guarantees consistency across different 3D lighting locations. Figure 8

Figure 6: Estimated environment maps and images with inserted relit virtual objects for scenes from our synthetic InteriorNet test set. The leftmost column displays the input reference image (our method also takes a second input image) and the portion of the environment map that is visible in this reference image (used to visualize the portion of the environment map which must be hallucinated in black). We display quantitative metrics (PSNR and RGB Angular Error) for the predicted environment maps below each method’s results. Our method outperforms all competing methods, both qualitatively and quantitatively, producing realistic environment maps with plausible unobserved regions. Inserted specular virtual objects relit with our environment maps have highlights and reflected colors that are closer to ground truth than those relit by baseline methods.
This is because it is much harder for their 2D completion CNN to learn meaningful implicit priors on environment maps since they can be observed with arbitrary rotations. In contrast, our strategy predicts lighting in a canonical 3D frame instead of in a 2D environment map pixel space, so it is much easier for our network to learn meaningful priors on the distribution of 3D lighting.

Please see our supplementary video and PDF for additional comparisons of relit inserted objects that showcase the temporal consistency and realistic spatially-varying illumination produced by our method.

6.2. Comparisons to ablations of our method

We also present quantitative results from two ablations of our method in Table 1. Our “MPI only” ablation only uses our prediction of observed scene geometry to render the spherical environment map (and fills unobserved regions with grey). In this case, the network cannot add light values to the unseen parts of the scene, so the resulting environment maps are largely incomplete. Since these missing regions are the most important for relighting objects inserted into the scene, we see a significant decrease in quality. Interestingly, our full method even outperforms the “MPI only” ablation for the observed content, which shows that our multiscale volume completion network learns to correct errors in MPI prediction. Our “No $L_{adv}$” ablation omits the adversarial loss when training the volume completion network. The resulting environment maps are slightly better quantitatively, but contain less high frequency detail, resulting in less realistic appearance when rendering glossy inserted objects. Please see our supplementary materials for qualitative results from these ablations.

7. Discussion

This paper demonstrates that using a persistent 3D lighting model of the scene is a compelling strategy for estimating spatially-coherent illumination from images. We have chosen a multiscale volumetric lighting representation to make this approach tractable and proposed a deep learning pipeline to predict this lighting representation using only images as supervision. Our results demonstrate that this strategy produces plausible spatially-coherent lighting and outperforms prior state-of-the-art work.

However, we have just touched the surface of possible 3D lighting representations for this task. An exciting direction would be to develop models that adaptively allocate 3D samples as needed to represent a scene, rather than being limited to a fixed multiresolution sampling pattern. We hope that this work enables future progress in predicting 3D scene representations for lighting estimation and other inverse rendering tasks.
