1. Introduction

We are surrounded by events that can be perceived via distinct audio and visual cues. Be it a ringing phone or a car passing by, we instantly identify the audio-visual (AV) components that characterize these events. This remarkable ability helps us understand and interact with our environment. For building machines with such scene understanding capabilities, it is important to design algorithms for learning audio-visual representations from real-world data. This work is a step in that direction, where we aim to learn such representations through weak supervision i.e., supervision only in the form of video-level event labels without any timing information.

To motivate our tasks and method, consider a video labeled as “train horn”. Assuming that the train is both visible and audible at some time in the video, in addition to identifying the event, we are interested in learning representations that help us answer the following questions:

- Where is the visual object or context that distinguishes the event? In this case it might be the train (object) or platform (context) etc. We are thus aiming for their spatio-temporal localization in the image sequence.

- When does the sound event occur? Here it is the train horn. We thus want to temporally localize the audio event.

The variety of noisy situations that one may encounter in unconstrained videos adds to the difficulty of this very challenging problem. Apart from modality-specific noise such as visual clutter or low audio SNR, in real-world scenarios, the audio and visual elements characterizing the event are often unsynchronized in time. This is to say that the train horn in the previous example may sound before or after the train is visible. In the extreme, not so rare case, the train may not appear at all. We are interested in designing a system to tackle the aforementioned questions and situations.

Prior research has utilized AV modalities for classification and localization tasks in various contexts. Fusing modality-specific hand-crafted or deep features has been a popular approach for problems such as multimedia event detection [5]. Lately, several inspiring multimodal deep networks have been proposed [7, 1], focusing primarily on unsupervised representation learning and synchronous AV training. However, to our knowledge, a unified framework for simultaneous event classification and characteristic AV cue localization, especially in asynchronous situations, has not been extensively studied in literature.

Our tasks can be naturally interpreted as multiple instance learning (MIL) problems [3]. MIL is typically applied to cases where labels are available over bags (sets of instances) instead of individual instances. The task then amounts to jointly selecting appropriate instances and estimating classifier parameters.

In our case, a video, $V$ can be decomposed as a bag of $M$ selected image regions, $R = \{r_1, r_2, \ldots, r_M\}$, obtained from sub-sampled frames and $T$ audio segments, $S = \{s_1, s_2, \ldots, s_T\}$. Each region/segment proposal is dealt with in separate visual & audio sub-modules. The key idea is to extract features from generated proposals and transform them for: (1) scoring each according to their relevance for class labels; (2) aggregating these scores in each modality & fusing them for video-level classification. This allows us to train both the sub-modules together through weak-supervision and learn representations for event classification and localization. Moreover, use of both the modalities makes the system robust against noisy scenarios.

An overview of our approach is provided in Fig. 1. For the visual network, we use class-agnostic bounding box proposals and for audio, short overlapping temporal segments. Following [2], we employ a parallel two-stream architec-
Table 1. Results on DCASE smart cars task test set. We report here the micro-averaged F1 score, precision and recall values and compare with state-of-the-art. TS is an acronym for two-stream.

3. Experiments

We validate the system’s performance, both quantitatively and qualitatively over DCASE challenge smart cars data [6], a large-scale multi-label weakly labeled dataset for audio events consisting of 17 classes, spread over approximately 50K YouTube videos from AudioSet [4].

**Baselines.** In Table 1, systems (b) and (c) only utilize the audio and visual sub-modules, respectively; (d) refers to the system proposed in [2]; (e) uses a single stream with log-sum-exp operator and (f)-(g) are systems from DCASE 2017 smart cars challenge event classification task winners [8], using only audio and no external data. All the systems are evaluated on the micro-averaged F1 score. This was the official metric used by the task organizers for ranking systems. For further insight, we also compute the class-wise F1 scores.

Table 1 shows event classification results for all the methods. Our system achieves state-of-the-art performance. We also find that the audio-visual complementarity is clearly reflected by the class-wise F1 scores (reported in the full paper). Briefly, the data can be categorized into two sets: (i) classes with well defined AV objects like car, motorcycle etc. and (ii) warning sounds, like, siren, car alarm. Well-defined visual cues enhance the performance of the proposed multimodal system over audio-only approaches. On the other hand, for warning sounds, frames alone are insufficient. For such cases, audio assists in improving system performance. Fig. 2 displays results for object localization in video frames and Fig. 3 illustrates an example of asynchronous AV cues.
