A. Content

In these supplementary materials we describe in further detail aspects of the dataset and the training process and performance of the tested methods. Specifically, the following will be described:

• Additional examples from the Sewer-ML dataset (Section B).
• Further insights into the Sewer-ML dataset (Section C).
• Full training details and metric performance for the Faster-RCNN text detector (Section D).
• Full details on the Extra Trees hyperparameter grid search (Section E).
• The loss curves of the trained multi-label classification methods (Section F).
• Ablation study of the two-stage methods (Section G).
• Results when evaluating using the common multi-label performance metrics (Section H).

B. Sewer-ML Dataset Examples

In this section we present more examples of the images in the Sewer-ML dataset. All images are annotated using the Danish inspection standard containing 18 classes [3], listed in Table 1. In Figure 1 we present examples of different cases with several co-occurring classes. In Figure 12 we present five examples of each class, where only the mentioned class is present.

C. Sewer-ML Dataset Insights

In this section, we describe the available information in the Sewer-ML dataset in more detail. First, we report the number of occurrences for each class in the dataset splits, see Table 2, where it is observed that the distribution of the classes is similar across the different splits.
pipe shapes for the images in each of the dataset splits. We find that the circular type is by far the most common pipe shape, followed secondly by conical pipes, whereas the remaining pipe shapes only appear a few thousand times each. As with the pipe material, we see that distribution of pipe shapes are similar between dataset splits, except for the “Eye shaped”, “Rectangular”, and “Other” pipe shapes. This is again due to these pipe shapes occurring in a limited set of sewer inspections, and have therefore not been evenly divided across the splits.

In Figure 4 we plot the occurrences of the pipe dimensions associated with each image. The dimension is denoted in millimeters, as per the industry standard. We see that the majority of images are from pipes with a diameter of 100–1,000 millimeters, with a skew towards 100 millimeters. We
observe that the distribution of the pipe dimension for the training, validation, and test splits appears to be similar in shape, as expected.

In Figure 5 we plot the distribution of the different water level classes for each data split. We find that the distribution of the water level classes is similar across the three dataset splits. We also observe that the majority of the images have an associated water level in the range 0–30 %, while the remaining classes occur less often, and not as evenly split between the classes. This can be explained by the fact that when the majority of a pipe is filled with water, the inspections may at times be postponed for a later time and it becomes difficult to accurately access how much water it actually contains. Furthermore, the inspection vehicle will at times be partially or fully submerged in the water, resulting in the inspector losing key reference points used for estimating the water level, such as the pipe wall.

Lastly, in Figure 6 we plot the resolution of the sewer inspection videos in each split. The resolution is denoted as width by height. It should be noted that the video resolutions reported are not the resolutions observed by the video camera.
inspector. The videos are encoded in such a way that the video data is stored in the resolution reported in this work, but when presented using a media player the width is multiplied by a “sample aspect ratio”. We decide not to apply this resizing, in order to not introduce artifacts in the image data. We find that across the videos in each dataset split, the resolutions are evenly distributed. This is also true when looking at the resolution for all the images in the dataset splits, see Figure 7.

Figure 7: Distribution of image resolution. We present the distribution of the different resolutions for the images in each dataset split. Note the y-axis is log-scaled.

Figure 6: Distribution of video resolution. We present the distribution of the different resolutions for the videos in each dataset split. Note the y-axis is log-scaled.

D. Faster-RCNN Training and Metric Details

In this section we detail the hyperparameters and training settings for the Faster-RCNN [15] model we use to redact overlaid text information on the images. We also present the full COCO [11] metric suite performance, to show how well the network performs. A training split of 20,739 images and a validation split of 2,305 images are used, wherein all text information is manually annotated with bounding boxes.

Hyperparameters. The Faster-RCNN model is trained for 26 epochs with a batch size of 16 batches. An SGD optimizer with momentum is used, with a learning rate of 0.02, momentum of 0.9 and weight decay of 0.0001. The learning rate is multiplied by 0.1 at epoch 16 and 22, respectively. We employ linear warm up of the learning rate during the first 1,000 mini batches of the first epoch, increasing the learning rate from $10^{-8}$ to 0.02. The backbone is a ResNet-50 FPN [7, 10] pre-trained on ImageNet [17], of which we fine-tune the last three residual blocks. Custom anchor boxes are used, with a bounding box ratios (height over width) of 1:8, 1:4 and 1:2, and bounding box scales with areas of $32^2$, $64^2$, $128^2$, $256^2$, and $512^2$. These values are determined based on the bounding box information in the training split, see Figure 8. All images are normalized using the ImageNet per channel mean and standard deviation, and horizontal flipping with a 50% chance is used during training. The images are rescaled such that the shortest side is 800 pixels, while enforcing that the largest side is no larger than 1,333 pixels. The training loss and mAP[0.5:0.95] on the validation set are plotted in Figure 9.

</tbody>
</table>

Figure 9: **Faster-RCNN loss and metric curves.** The training loss and validation metrics for the trained Faster-RCNN model. mAP@[0.5:0.95] is denoted as mAP.

**Metrics.** In order to determine the effect of the Faster-RCNN model, we compute the full COCO metrics suite on the validation set, as shown in Table 3. As shown in the metrics, we have a high precision and recall, though the recall indicates that not all of the text objects have been detected. This is partially due to some text information being annotated with a single bounding box but detected as several boxes, and vice versa. To verify the annotations we manually inspect a set of randomly selected samples.

**E. Extra Trees Hyperparameter Grid Search**

For the system proposed by Myrans et al. [13, 14], two Extra Trees classifiers are used in sequence. However, the hyperparameters of the trees are not specified. Therefore, we conduct a small grid search across three hyperparameters: The amount of trees in the ensemble, the maximum depth of the trees, and the maximum amount of features used when splitting an internal node. The investigated parameters are reported in Table 4. We train the Extra Trees classifier in three settings. First, we train under a binary setting determining whether there is any class in the image. Thereafter, we train a multi-label setting, first on a subset of the dataset only containing images with annotated classes, and secondly on the full dataset. The resulting validation losses of the hyperparameter search is shown in Figure 10. From this we conclude that for the binary Extra Trees classifier 100 trees, with a maximum depth of 10 and using \( \log_2(d) \) features when splitting, should be used. Similarly, we find that for the multi-label Extra Trees classifiers 250 trees, with a maximum depth of 10 and using \( \log_2(d) \) features when splitting, should be used.

**F. CNN Loss Curves**

We present the loss curves for all the tested convolutional neural networks (CNNs) tested, see Figure 11. All networks are trained using the weighted binary cross-entropy loss, and using hyperparameters set based on the guidelines from Goyal et al. [5]. Further training details are presented in the main manuscript.

From the loss plots we observe that the validation loss of the majority of the tested networks start diverging after approximately 30-40 epochs, a clear sign of overfitting. The method by Xie et al. [19] is an exception, with the first and second stage methods stagnating after 60–70 epochs. We also observe that the first stage of Chen et al. [1], the SqueezeNet [8], has a constant loss value for both the training and validation loss. Similarly, the second stage of Xie et al. settles on a constant loss after the initial 10 epochs when trained on the full dataset.
Figure 10: Extra Trees grid search results. Results of the grid search of the Extra Trees classifiers for: Binary classifier trained on full dataset, multi-label classifier trained on a subset of the dataset, and multi-label classifier trained on the full dataset.

G. Two-Stage Ablation Study

We conduct two ablation studies on the two-stage classifiers, to determine the effect of the different stages and training methodology.

What is the effect of the binary classifier? We compare the effect on performance of using both stages or only the second stage. These results are presented in Table 5, and indicate that the first stage is crucial. Performance for Xie et al. [19] degrades for both metrics when the first stage is missing, whereas for Chen et al. [1] there is no difference as the first stage never predicts a normal pipe. For Myrans et al. [13] the first stage inaccurately classifies images with classes as normal pipes, causing a lower F2CIW score. This is improved when using only the second stage, but at the cost of an inability to recognize any normal pipes.

Training the second stage on the full dataset. Classically within the sewer classification domain, the second stage is only trained on data which contains some kind of class. We investigate whether performance improves by training on the full dataset, such that the second stage also sees normal pipes. The results are shown in Table 6. For Myrans et al. the performance is reduced substantially in both tested settings, and the second stage is still unable to classify normal pipes. For Xie et al. both metrics are lower when comparing to Table 5, except for the large increase in FNormal score when only using the second stage. The only performance improvement is achieved by Chen et al. through the use of the deeper InceptionV3 network.

H. Multi-Label Metrics and Results

When evaluating multi-label tasks, a large suite of metrics are commonly used, in order to uncover different aspects of the tested methods. Commonly, the F1-score is used in different variations, depending on how the F1-score is calculated or averaged. An overview of the different metrics is provided in Table 8. Each of the metrics are in the range [0, 1], and for all a high score is better. As a reference on how to compute the metrics, we refer to the supplementary materials of the work by Durand et al. [4]. We present the classic performance metrics for each of the tested methods on both the validation and test splits, as well as the per-class F1, F2, Recall, Precision, and Average Precision (AP). It should be noted, that AP cannot be calculated for the normal class. This is due to the normal class being an implicit class, and therefore not possible to rank as it does not have a single associated probability. The Kumar et al. [9], Meijer et al. [12] and ML-GCN [2] methods are not shown in the metric tables as the models diverged during training. The benchmark algorithm consisting of the first stage from Xie et al. [19] and the TResNet-L multi-label classifier [16] is reported as “Benchmark”. The metrics for the validation split are presented in Table 9-14 and the metrics for the test split are presented in Table 15-20.
