Abstract

Novel-view synthesis through diffusion models has demonstrated remarkable potential for generating diverse and high-quality images. Yet, the independent process of image generation in these prevailing methods leads to challenges in maintaining multiple view consistency. To address this, we introduce ViewFusion, a novel, training-free algorithm that can be seamlessly integrated into existing pre-trained diffusion models. Our approach adopts an auto-regressive method that implicitly leverages previously generated views as context for next view generation, ensuring robust multi-view consistency during the novel-view generation process. Through a diffusion process that fuses known-view information via interpolated denoising, our framework successfully extends single-view conditioned models to work in multiple-view conditional settings without any additional fine-tuning. Extensive experimental results demonstrate the effectiveness of ViewFusion in generating consistent and detailed novel views.

1. Introduction

Humans have a remarkable capacity for visualizing unseen perspectives from just a single image view – an intuitive process that remains complex to model. Such an ability is known as Novel View Synthesis (NVS) and necessitates robust geometric priors to accurately infer three-dimensional details from flat imagery; lifting from a two-dimensional projection to a three-dimensional form involves assumptions and knowledge about the nature of the object and space. Recently, significant advancements in NVS have been brought forward by neural networks [14, 15, 30, 41, 60, 64, 65, 72, 75, 76], where novel view generation for downstream reconstruction shows promising potential [34, 69].

Specifically, diffusion models [19, 51] and their ability to generate high-quality 2D images have garnered significant attention in the 3D domain, where pre-trained, text-conditioned 2D diffusion models have been re-purposed for 3D applications via distillation [4, 31, 40, 47, 49, 57, 63,

---

(a) Inconsistent generation.   (b) Consistent generation (ours).

Figure 1. The cause of multi-view inconsistency in diffusion-based novel-view synthesis models. (a) Diffusion models incorporate randomness for diversity and better distribution modeling; this independent generation process produces realistic views under specific instances but may produce different plausible views for various instances, lacking alignment across adjacent views. (b) In contrast, ViewFusion incorporates an auto-regressive process to reduce uncertainty and achieve multi-view consistency, by ensuring a correlated denoising process that ends at the same high-density area, fostering consistency across views.

68, 73]. Follow-up approaches [34, 69] remove the requirement of text conditioning and instead take an image and target pose as conditions for NVS. However, distillation [63] is still required as the diffusion model cannot produce the multi-view consistent outputs that are appropriate for certain downstream tasks (*e.g.*, optimizing Neural Radiance Fields (NeRFs) [41]).

Under the single-view setting, maintaining multi-view consistency remains particularly challenging since there may exist several plausible outputs for a novel view that are aligned with the given input image. For diffusion-based approaches which generate novel views in an independent manner [34, 69], this results in synthesized views containing artifacts of multi-view inconsistency (Fig. 1a). Previous work [33, 36, 38, 53, 74, 77] focuses on improving the robustness of the downstream reconstruction to address the inconsistency issue, including feature projection layers in the NeRF [33] or utilising three-dimensional priors to constrain NeRF optimization [36, 77], yet these techniques require training or fine-tuning to align additional modules to the original diffusion models.

In this work, we address the multi-view inconsistency that arises during the process of view synthesis. Rather than

independently synthesizing views conditioned only on the initial reference image, we develop a novel approach where each subsequently generated view is also conditioned on the *entire set* of previously generated views. Specifically, our method incorporates an auto-regressive process into the diffusion process to model the joint distribution of views, guiding our novel-view synthesis by maintaining the denoising direction towards the same high density area of already generated views (Fig. 1b).

Our framework, named ViewFusion, relaxes the single-view conditioning requirement of typical diffusion models through an interpolated denoising process. ViewFusion offers several additional advantages: 1) it can utilize all available views as guidance, thereby enhancing the quality of generated images by incorporating more information; 2) it does not require any additional fine-tuning, effortlessly converting pre-trained single-view conditioned diffusion models into multi-view conditioned diffusion models; 3) it provides greater flexibility in setting adaptive weights for condition images based on their relative view distance to the target view.

The contributions of this paper are the following:

- We propose a *training-free* algorithm which can be directly applied to pre-trained diffusion models to improve multi-view consistency of synthesized views and supports multiple conditional inputs.
- Our method utilizes a novel, auto-regressive approach which we call *Interpolated Denoising*, that implicitly addresses key limitations of previous auto-regressive approaches for view synthesis.
- Extensive empirical analysis on ABO [6] and GSO [9] show that our method is able to achieve better 3D consistency in image generation, leading to significant improvements in novel view synthesis and 3D reconstruction of shapes under single-view and multi-view image settings over other baseline methods.

2. Related Work

2.1. 3D-adapted Diffusion Models

Diffusion models have excelled in image generation using conditional inputs [20, 46, 50, 84] and given this success in the 2D domain, recent works have tried to extend diffusion models to 3D content generation [1, 3, 5, 10, 16, 18, 22, 24, 25, 27, 37, 43–45, 66, 82, 83] – although the scarcity of 3D data presents a significant challenge to directly train these diffusion models. Nonetheless, pioneer works such as DreamFusion [47] and Score Jacobian Chaining [63] leverage pre-trained text-conditioned diffusion models to craft 3D models via distillation. Follow-up approaches [4, 31, 57, 68] improve this distillation in terms of speed, resolution and shape quality. Approaches such as [40, 49, 57, 73] extend upon this to support image condi-

tions through the use of captions with limited success due to the non-trivial nature of textual inversion [13].

2.2. Novel View Synthesis Diffusion Models

Another line of research [2, 8, 17, 28, 35, 56, 58, 61, 62, 69, 71, 78, 80, 86] directly applies 2D diffusion models to generate multi-view images for shape reconstruction. To circumvent the weakness of text-conditioned diffusion models, novel-view synthesis diffusion models [34, 69] have also been explored, which take an image and target pose as conditions to generate novel views. However, for these approaches, recovering a 3D consistent shape is still a key challenge. To mitigate 3D inconsistency, Liu et al. [33] suggests training a Neural Radiance Field (NeRF) with feature projection layers. Concurrently, other works [36, 38, 70, 74, 77] add modules to original diffusion models for multi-view consistency, including epipolar attention [77], synchronized multi-view noise predictor [36] and cross-view attention [38, 70]; although these methods require fine-tuning an already pre-trained model. We adopt a different paradigm, instead of extending a single-view diffusion model with additional trainable models that incorporate multi-view conditions, our training-free method enables pre-trained diffusion models to incorporate previously generated views via the denoising step and holistically extends these models into multi-view settings.

2.3. Other Single-view Reconstruction Methods

Before the prosperity of generative models used in 3D reconstruction, many works [11, 12, 14, 15, 26, 29, 30, 59, 64, 75] reconstructed 3D shapes from single-view images using regression [14, 15, 29, 64, 75] or retrieval [59], both of which face difficulties in generalizing to real data or new categories. Methods based on Neural Radiance Fields (NeRFs) [41] have found success in novel-view synthesis, but these approaches typically depend on densely captured images with accurately calibrated camera positions. Currently, several studies are investigating the adaptation of NeRF to single-view settings [21, 32, 52, 79]; although, reconstructing arbitrary objects from single-view images is still a challenging problem.

3. Method

3.1. Denoising Diffusion Probabilistic Models

Denoising diffusion probabilistic models (DDPM) [19, 54] are a class of generative models that model the real data distribution $q(x_0)$ with a tractable model distribution $p_\theta(x_0)$ by learning to iteratively denoise samples. It learns a probability model $p_\theta(\mathbf{x}_0) = \int p_\theta(\mathbf{x}_{0:T}) d\mathbf{x}_{1:T}$ to convert unstructured noise $\mathbf{x}_T$ to real samples $\mathbf{x}_0$ in the form of a Markov chain, with Gaussian transitions. The Gaussian transition is
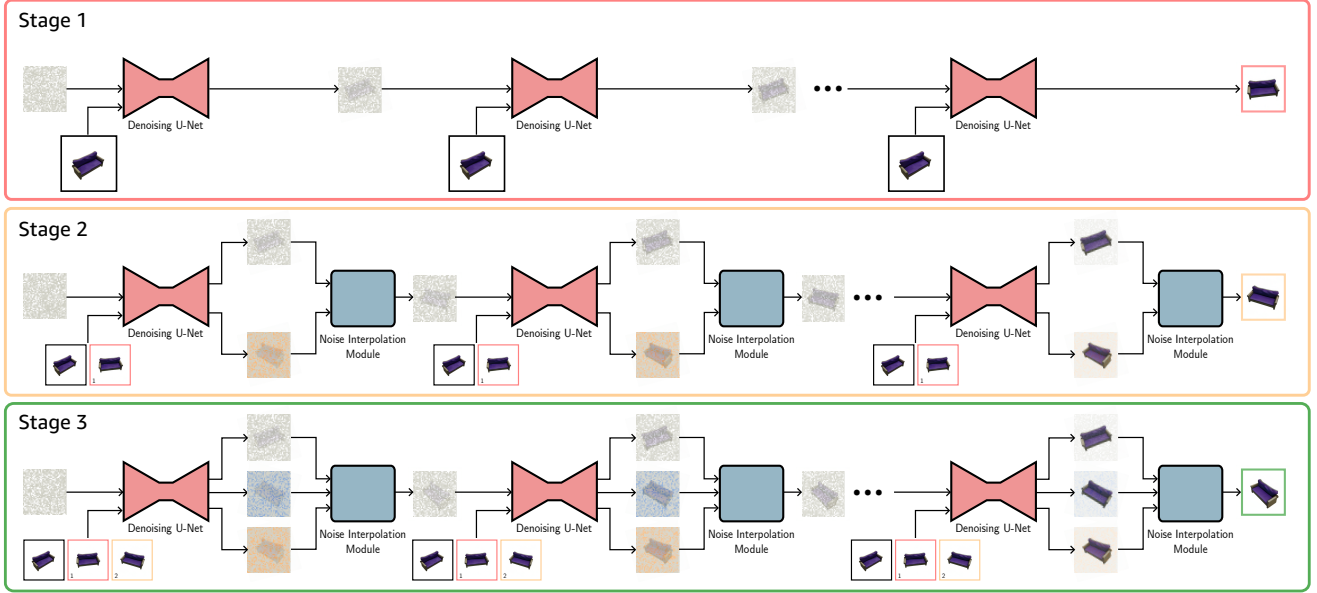

Figure 2. Illustration of the Auto-Regressive Generation Process. In our approach, we extend a pre-trained diffusion model from single-stage to multi-stage generation and we maintain a view set that contains all generated views. For each stage, we construct N reverse diffusion processes and sharing a common starting noise. At each time step within this generation stage, the diffusion model predicts N noises individually. These N noises are then subjected to weighted interpolation through the *Noise Interpolation Module*, concluding the denoising step with the a shared interpolated noise for subsequent denoising steps.

defined as:

$$q(\mathbf{x}_T|\mathbf{x}_0) = \prod_{t=1}^{T} q(\mathbf{x}_t|\mathbf{x}_{t-1}) = \prod_{t=1}^{T} \mathcal{N}(\mathbf{x}_t; \sqrt{1-\beta_t}\mathbf{x}_{t-1}, \beta_t\mathbf{I}),$$
(1)

where $\beta_t, t \in \{1, ..., T\}$ are the variance schedule parameter and timestep in the denoising process respectively. The reverse denoising process starts from a noise sampled from a Gaussian distribution $q(\mathbf{x}_T) = \mathcal{N}(\mathbf{0}, \mathbf{I})$ and is constructed as:

$$p_\theta(\mathbf{x}_0|\mathbf{x}_T) = \prod_{t=1}^{T} p_\theta(\mathbf{x}_{t-1}|\mathbf{x}_t) = \prod_{t=1}^{T} \mathcal{N}(\mathbf{x}_{t-1}; \mu_\theta(\mathbf{x}_t, t), \sigma_t^2\mathbf{I}),$$
(2)

where the variance σ_t^2 is a time-dependent constant [19], and $\mu_\theta(\mathbf{x}_t, t)$ is the mean from the learned *noise predictor* ϵ_θ:

$$\mu_\theta(\mathbf{x}_t, t) = \frac{1}{\sqrt{\alpha_t}} \left(\mathbf{x}_t - \frac{\beta_t}{\sqrt{1-\bar{\alpha}_t}} \epsilon_\theta(\mathbf{x}_t, t) \right).$$
(3)

Here, α_t and $\bar{\alpha}_t$ are constants derived from β_t. The objective of noise predictor ϵ_θ is simplified to:

$$\ell = \mathbb{E}_{t, \mathbf{x}_0, \epsilon} \left[\| \epsilon - \epsilon_\theta(\sqrt{\bar{\alpha}_t}\mathbf{x}_0 + \sqrt{1-\bar{\alpha}_t}\epsilon, t) \|_2 \right],$$
(4)

where ϵ is a random variable sampled from $\mathcal{N}(\mathbf{0}, \mathbf{I})$ [19].

3.2. Pose-Conditional Diffusion Models

Similar to other generative models [42, 55], diffusion models inherently possess the capability to model conditional distributions of the form $p_\theta(x_{t-1}|x_t, y)$ where y is the condition. We employ a conditional denoising autoencoder, denoted as $\epsilon_\theta(\mathbf{x}_t, t, y)$ which enables controlling the synthesis process through a variety of input modalities, including textual descriptions [50], semantic maps [20, 46], or other image-to-image translation tasks [20]. In the following, we present a range of approaches to novel-view synthesis, exploring how various works, including our own, approach the concept of a single reverse diffusion step. Through this comparison, we clarify and establish the underlying relationships between these different methodologies. The notation will follow that bottom subscript $(\cdot)_t$ indicates the diffusion step and upper subscript $(\cdot)^i$ relates to the view index. Subsequently, the i-th condition image and its relative pose to the target view are defined as $\mathbf{y}^i$ and π^i, respectively, and the noisy image to be denoised at timestep t is defined as $\mathbf{x}_t$.

Direct condition was applied by Zero 1-to-3 [34] to the reverse process when given a single input image and target pose $\mathbf{y}^1, \pi^1$:

$$p(\mathbf{x}_{t-1}|\mathbf{x}_t, \mathbf{y}^1, \pi^1).$$
(5)

Stochastic conditioning was formulated by [69] which can leverage multiple views sampled from a collection of views $p_{\mathbf{y},\pi}(\mathcal{Y}, \pi)$:

$$p(\mathbf{x}_{t-1}|\mathbf{x}_t, \mathbf{y}^i, \pi^i), \{\mathbf{y}^i, \pi^i\} \sim p_{\mathbf{y},\pi}(\mathcal{Y}, \pi),$$
(6)

where the sampling of image and pose happens at each diffusion step t.

Joint output distribution was shown in SyncDreamer[36] which learns a joint distribution of many views given an image condition y^1:

$$p(\mathbf{x}_{t-1}^{1:N}|\mathbf{x}_t^{1:N}, \mathbf{y}^1, e^1), \tag{7}$$

where N is the number of generated novel views and e is the elevation condition (partial pose information). We note that in this formulation the target poses are not fully specified as part of the condition allowing for diverse pose generation of outputs.

Auto-regressive distribution is an auto-regressive distribution setting which can generate an arbitrary number of views given a single or multiple condition images and poses contained in the set of $\mathbf{y}^{1:N-1}, \pi^{1:N-1}$:

$$p(\mathbf{x}_{t-1}^N|\mathbf{x}_t^N, \mathbf{y}^{1:N-1}, \pi^{1:N-1}). \tag{8}$$

Our approach falls in the auto-regressive category and for the remainder of this section we detail the implementation to achieve this sampling strategy.

3.3. Interpolated Denoising

The standard DDPM model has been adapted for novel-view image synthesis by using an image and target pose (*i.e.*, rotation and translation offsets) as conditional inputs [69]. Following training on a large-scale dataset, this approach has demonstrated the capability for zero-shot reconstruction [34]. To address the challenge of maintaining multi-view consistency, we employ an auto-regressive approach for generating sequential frames (See Fig. 2). Instead of independently producing each frame from just the input images – a process prone to significant variations between adjacent images – we integrate an auto-regressive algorithm into the diffusion process. This integration enables us to model a conditional joint distribution, ensuring smoother and more consistent transitions between frames.

To guide the synthesis of novel views using images under different views, we design an interpolated denoising process. For the purpose of this derivation, we assume access to an image set containing $N - 1$ images denoted as $\{\mathbf{y}^1, ..., \mathbf{y}^{N-1}\}$. We want to model the distribution of the N-th view image conditioned on these $N - 1$ views $q(\mathbf{x}_{1:T}^N|\mathbf{y}^{1:N-1})$, where the relative pose offsets $\pi^i, i \in \{1, N - 1\}$ between the condition images $\{\mathbf{y}^1, ..., \mathbf{y}^{N-1}\}$ and target image $\mathbf{x}_0^N$ are omitted for simplicity. The forward process of the multi-view conditioned diffusion model

is a direct extension of the vanilla DDPM in Eq. 1, where noises are added to every view independently by

$$q(\mathbf{x}_{1:T}^N|\mathbf{y}^{1:N}) = \prod_{t=1}^T q(\mathbf{x}_t^N|\mathbf{x}_{t-1}^N, \mathbf{y}^{1:N}) \tag{9}$$

where $q(\mathbf{x}_t^N|\mathbf{x}_{t-1}^N, \mathbf{y}^{1:N}) = \mathcal{N}(\mathbf{x}_t^N; \sqrt{1-\beta_t}\mathbf{x}_{t-1}^N, \beta_t\mathbf{I})$. The initial is defined as $\mathbf{x}_0^N := \mathbf{y}^N$. Similarly, following Eq. 2, the log reverse process is constructed as

$$
\begin{aligned}
\log p_\theta(\mathbf{x}_0^N|\mathbf{x}_T^N, \mathbf{y}^{1:N-1}) &= \sum_{t=1}^T \log p_\theta(\mathbf{x}_{t-1}^N|\mathbf{x}_t^N, \mathbf{y}^{1:N-1}) \\
&\underset{(1)}{\approx} \sum_{t=1}^T \log \prod_{n=1}^{N-1} p_\theta(\mathbf{x}_{t-1}^N|\mathbf{x}_t^N, \mathbf{y}^n) \\
&= \sum_{t=1}^T \sum_{n=1}^{N-1} \log \mathcal{N}(\mathbf{x}_{t-1}^N; \mu_\theta^n(\mathbf{x}_t^N, \mathbf{y}^n, t), \sigma_t^2\mathbf{I}) \\
&= \sum_{t=1}^T \mathcal{N}\left(\mathbf{x}_{t-1}^N; \bar{\mu}_\theta(\mathbf{x}_t^N, \mathbf{y}^{1:N-1}, t), \bar{\sigma}_t^2\mathbf{I}\right).
\end{aligned}
\tag{10}
$$

Where $\bar{\mu}_\theta, \bar{\sigma}_t^2$ are taken as the mean and variance of the summation of $N - 1$ *log*-normal distributions. A note on subscript (1) in Eq.10; to avoid cluttering the derivation, we assume $N - 1$ independent inferences of the same random variable $\mathbf{x}_{t-1}^N$ using *a different* $\mathbf{y}^n$ that results in $N - 1$ independent normal distributions, which would require an additional subscript that we omitted for clarity.

3.4. Single and Multi-view Denoising

In practice, however, we may not have all $N - 1$ views but a single view or a handful of views. For the reminder of this section, we treat an estimated view as $\mathbf{x}_0^n$, to be the n-th view $\mathbf{y}^n$ after a full reverse diffusion process. We use $\bar{\mu}_\theta(\mathbf{x}_t, \mathbf{y}^{1:N-1}, t)$ as the weighted average of $\mu_\theta^n(\mathbf{x}_t, \mathbf{y}^n, t)$. For computing $\bar{\mu}_\theta$ using both given views and estimated views we adopt an approach where different views contribute differently to the target view, and we assign the weight ω_n for the n-th view in practice while satisfying the constraint $\sum_{n=1}^{N-1} w_n = 1$. The *Noise Interpolation Module* in Fig. 2 is modeled as:

$$
\begin{aligned}
\bar{\mu}_\theta(\mathbf{x}_t, \mathbf{y}^{1:N-1}, t) &= \sum_{n=1}^{N-1} \omega_n \mu_\theta^n(\mathbf{x}_t, \mathbf{y}^n, t) \\
&= \sum_{n=1}^{N-1} \omega_n \frac{1}{\sqrt{\alpha_t}}\left(\mathbf{x}_t - \frac{\beta_t}{\sqrt{1-\bar{\alpha}_t}}\epsilon_\theta(\mathbf{x}_t, \mathbf{y}^n, t)\right) \\
&= \frac{1}{\sqrt{\alpha_t}}\left(\mathbf{x}_t - \frac{\beta_t}{\sqrt{1-\bar{\alpha}_t}}\sum_{n=1}^N \omega_n \epsilon_\theta(\mathbf{x}_t, \mathbf{y}^n, t)\right).
\end{aligned}
\tag{11}
$$

In our approach, as the full view set is not given to us, we approximate this process by an auto-regressive way and

grow the condition set during the generation. We define the weight parameter ω_n based on the angle offset, *i.e.*, azimuth (Δ_a^n), elevation (Δ_e^n), and distance (Δ_d^n), between the target view and the $n-th$ condition view. The core idea is to assign higher importance to near-view images during the denoising process while ensuring that the weight for the initial condition image does not diminish too rapidly, even when the target view is positioned at a nearly opposite angle. We use an exponential decay weight function for the initial condition image, defined as $\omega_n = e^{-\frac{\Delta^n}{\tau_c}}$. Here, τ_c is the temperature parameter that regulates the decay speed, and Δ^n is the sum of the absolute relative azimuth (Δ_a^n), elevation (Δ_e^n), and distance (Δ_d^n) between the target and condition poses. We calculate Δ^n as $\Delta^n = |\Delta_a^n|/\pi + |\Delta_e^n|/\pi + |\Delta_d^n|$.

For the weights of the remaining images denoted as $\{x_0^2, ..., x_0^N\}$, all generated from the initial condition image $y^1 := x_0^1$, we use a softmax function to define the weights ω_n:

$$\omega_n = \text{Softmax}\left(\frac{e^{-\frac{\Delta^n}{\tau_g}}}{\sum_{n=2}^{N} e^{-\frac{\Delta^n}{\tau_g}}}\right), n = 2, ..., N \quad (12)$$

Similarly, Δ_n represents the relative pose offset between target view and the n-th generated view, and τ_g represents the temperature parameter for generated views. As an example, in the single-view case, the weights are expressed as follows,

$$\omega_n = \begin{cases} exp\left(-\frac{\Delta^n}{\tau_c}\right), & n = 1 \\ (1-\omega_1)\text{Softmax}\left(\frac{e^{-\frac{\Delta^n}{\tau_g}}}{\sum_{n=2}^{N} e^{-\frac{\Delta^n}{\tau_g}}}\right), & n \neq 1 \end{cases} \quad (13)$$

we apply the term $1 - \omega_1$ on the generated image weights to ensure the requirement of $\sum_{n=1}^{N-1} w_n = 1$ will be met. In practice, Eq.13 is generalised to allow the condition set can be larger than 1, *i.e.*, multi-view generation (see supplementary).

3.5. Step-by-step Generation

Single image generation. When applying the auto-regressive approach to image generation, we have devised a generation trajectory, as illustrated in Fig. 3a. We uniformly sample views along this trajectory in sequence. Each previously generated view image on this trajectory is incorporated into the condition set, providing guidance for the subsequent denoising process via our interpolated denoising method. To determine the number of steps, denoted as S, needed for this trajectory, we use the following formula:

$$S = max\left(\lceil\frac{\Delta_a^N}{\delta}\rceil, \lceil\frac{\Delta_e^N}{\delta}\rceil\right). \quad (14)$$
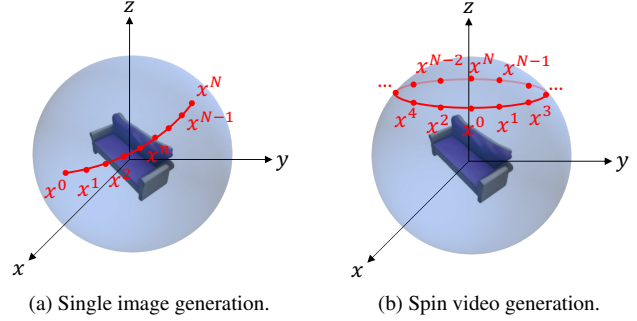

(a) Single image generation. (b) Spin video generation.

Figure 3. Illustration of Step-by-step Generation. (a) we uniformly sample views along this trajectory in sequence to generate a novel-view image; (b) we sample views from nearest to furthest views according to to view distance to generate a $360°$ spin video.

Here, we set the maximum offset per step δ to determine the step count S, also based on the target view offsets Δ_a^N and Δ_e^N. We then proceed to sample the n-th view using the following equation:

$$(\Delta_a^n, \Delta_e^n, \Delta_d^n) = \left(\frac{\Delta_a^N}{S} * n, \frac{\Delta_e^N}{S} * n, \frac{\Delta_d^N}{S} * n\right) \quad (15)$$

Spin videos generation. In contrast to generating a single target image, the process of spin video generation begins from an initial image and concludes at the same position. To achieve this, we need to modify the generation order to leverage the broad range of rotation images, rather than simply following the rotation degree range of $[0°, 360°]$ in sequence. This is because, at $\Delta_a = \pi$, the view is opposite to the conditioning view, marking the end of the generation process. To establish the generation order for spin video generation, we introduce the minimum azimuth offset, denoted as δ, and employ a skip trajectory with the following order: $\{\delta, -\delta, 2\delta, -2\delta..., N\delta\}$, shown in Fig. 3b. For simplicity, we only consider rotation along the azimuth dimension in this context.

4. Experiments

Datasets. We evaluate our method and compare to baselines on the ABO [6] and GSO [9] datasets. These datasets are out-of-the-distribution as all baselines are trained on the Objaverse [7]. We also provide qualitative results on real images to showcase performance of our method on in-the-wild images in the supplementary. For additional results, please refer to the videos contained in the supplementary.

Metrics. We assess our novel-view synthesis on three main criteria:
1. *Image Quality*: LPIPS [85], PSNR, and SSIM [67] metrics to help gauge the similarity between synthesized and ground-truth views.

Dataset	Method	Free Renderings			SyncDreamer Renderings		
		SSIM↑	PSNR↑	LPIPS↓	SSIM↑	PSNR↑	LPIPS↓
ABO	Zero123 [34]	0.8796	21.33	0.0961	0.7822	18.27	0.1999
	SyncDre. [36]	0.7712	13.43	0.2182	**0.8031**	**19.07**	**0.1816**
	Ours	**0.8848**	**21.43**	**0.0923**	0.7983	18.75	0.1985
GSO	Zero123 [34]	0.8710	20.33	0.1029	0.7925	18.06	0.1714
	SyncDre. [36]	0.8023	14.42	0.1833	0.8024	18.20	**0.1647**
	Ours	**0.8820**	**20.73**	**0.0958**	**0.8076**	**18.40**	0.1703

Table 1. Quantitative results on ABO and GSO datasets with **arbitrary** (left) and **discrete** (right) rotation and translation. Free renderings are a set of arbitrary rotation and translation as target generation view, while SyncDreamer renderings are a fixed set of 16 views with discrete azimuth, fixed elevation and distance, *i.e.*, azimuth$\in \{0°, 22.5°, 45°, ..., 315°, 337.5°\}$, elevation=30°. Note that SyncDreamer [36] *cannot* generate images under arbitrary views apart from the predefined 16 camera positions.

2. *Multi-View Consistency*: Using SIFT [39], LPIPS [85] and CLIP [48], we measure the uniformity of images across various perspectives.
3. *3D Reconstruction*: Chamfer distances and F-score between ground-truth and reconstructed shapes determine geometrical consistency.

4.1. Novel-view synthesis

In Tab. 1, we show quantitative results for novel-view synthesis under arbitrary and fixed-view settings. The fixed-view setting uses the rendering set of [36] and ensures a fair comparison to [36] which is limited to this fixed-view generation setting. As shown in Tab. 1, our method can produce comparable results to [36], without any fine-tuning on the rendering set of [36]. Under the arbitrary-view setting, we sample the nearest view from the rendering set of [36] to the designated target view for generation; [36] underperforms both [34] and our approach. Overall, regardless of the evaluation setting, our method consistently outperforms [34] and even outperforms [36] on the GSO dataset under the favourable fixed-view setting for [36].

The task of novel view synthesis serves as a precursor for enabling more significant downstream applications, such as 3D reconstruction, by generating requisite input views. Thus, in addition to image quality, thorough evaluation needs to encompass the multi-view consistency of the synthesized perspectives. This additional criterion ensures that the generated imagery not only appears visually compelling but also aligns geometrically across different viewpoints. In the following sections, we evaluate against baselines on 3D consistency and show that the significant improvements our approach offers.

Multi-view Consistency. For measuring multi-view consistency of synthesized views, quantitative results are shown in Tab. 2, while qualitative comparisons are shown in Figs. 4 and 5. Here, we can see when compared to the baselines of [34] and [36], our approach excels in generating images

Dataset	Method	View	SIFT↑	LPIPS↓	CLIP↑
ABO	Zero123 [34]	16	13.38	0.1782	0.9604
	SyncDreamer [36]		12.36	0.1895	0.9584
	Ours		**13.51**	**0.1602**	**0.9664**
	Zero123 [34]	36	17.03	0.1231	0.9725
	Ours		**18.01**	**0.0966**	**0.9812**
GSO	Zero123 [34]	16	12.58	0.1411	0.9482
	SyncDreamer [36]		13.24	0.1315	0.9532
	Ours		**13.83**	**0.1187**	**0.9601**
	Zero123 [34]	36	15.20	0.1056	0.9592
	Ours		**17.95**	**0.0676**	**0.9773**

Table 2. Quantitative results for multi-view consistency. We report the SIFT matching point number, LPIPS and CLIP similarity between adjacent frames to evaluate the multi-view consistency. Note that SyncDreamer can only generate 16 view images for a spin video due to the constraints imposed by its training.

	Ours (3 views)	**0.8979**	**21.95**	**0.0792**

Table 3. Quantitative results for multi-conditioned generation. Our approach outperforms the Zero-1-to-3 baseline [34] by extending its single-view reconstruction framework to a multi-view reconstruction framework. Note that 3 condition views are removed from test set, and thus the results are slightly different to Tab. 1.

that are both semantically consistent with the input image and maintains multi-view consistency in terms of colors and geometry under arbitrary-view settings.

4.2. Multi-view conditional setting for NVS.

Additionally, our approach allows for the extension of single-view conditioned models into multi-view conditioned models which can take multiple conditional images as input. The results presented in Tab. 3 showcase the advantages our method offers, as novel-view synthesis quality improves with an increasing number of conditional input views. This is a significant improvement over the Zero-1-to-3 baseline and demonstrates the efficacy of our proposed method in the multi-view setting.

4.3. 3D Reconstruction

For shape reconstruction, we present our results both quantitatively (Tab. 4) and qualitatively (Fig. 6). We compare against baselines which synthesize novel views as well as direct image-to-shape approaches [23, 44]. For the former approach, instead of using distillation [63], we train NeuS [65] on synthesized images to recover a shape.
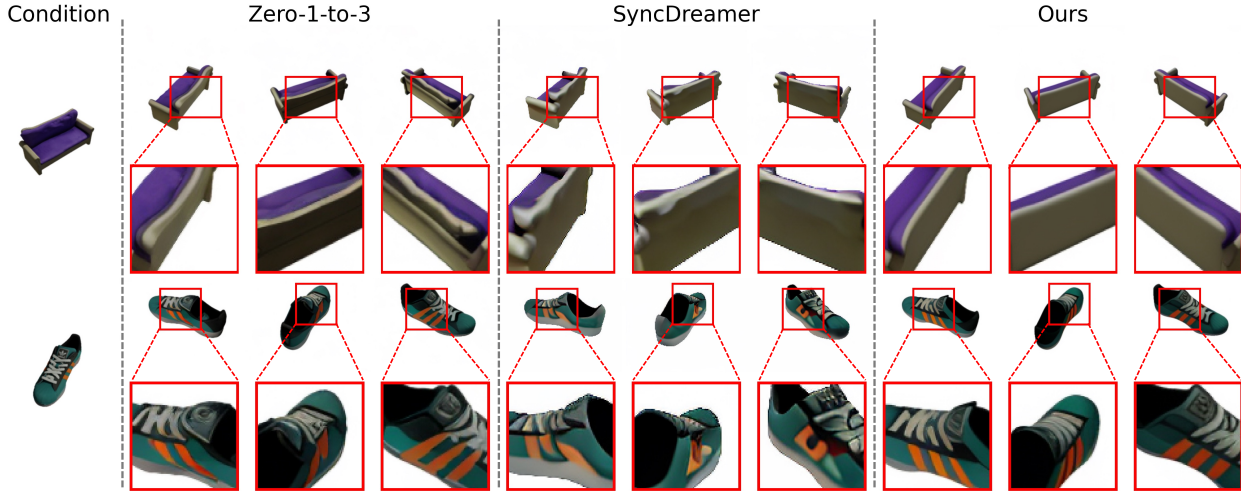

Figure 4. Qualitative results for 360° Spin Video Generation. Note the additional consistency in generated views our approach offers over the competing baselines shown in the bounding boxes.

Figure 5. Qualitative comparison for Motion Smoothness. We visualize the output videos using space-time Y-t slices through frames of the generated spin video (along the scanline shown in the condition).

Single-view Reconstruction. We first compare our proposed method with several baselines under the single-view reconstruction setting, including Point-E [44] and Shap-E [23], Zero-1-to-3 [34], One-2-3-45 [33] and Sync-Dreamer [36]. Qualitative results are shown in Fig. 6; Point-E and Shap-E tend to generate incomplete shapes due to the single-view setting. Multi-view alignment methods such as Syncdreamer [36] and One-2-3-45 [33] capture the general geometry but tend to lose fine details. In comparison, our proposed method achieves the highest reconstruction quality amongst all approaches, where we can generate smooth surfaces and capture detailed geometry with precision.

Multi-view Reconstruction Given our approach can also synthesis novel views under the multi-view setting, we also show results where we use 3 conditional input views to synthesize 36 views for shape reconstruction. Compared with existing multi-view reconstruction frameworks such as

Cond. views	Method	Gen. views	ABO		GSO	
			CD↓	F-score↑	CD↓	F-score↑
1	Point-E [44]	N/A	0.0428	0.7144	0.0672	0.6340
	Shap-E [23]	N/A	0.0466	0.7364	0.0384	0.7313

Table 4. Quantitative results on reconstructing 3D Shapes using the generated images.

Dataset	Method	SSIM↑	PSNR↑	LPIPS↓
ABO	Zero123 (no interp.)	0.8796	21.33	0.0961
	Standard auto-regression	0.8010	16.77	0.1854
	Interpolated conditions	0.7243	13.26	0.3770
	Interpolated outputs	**0.8925***	**21.95***	0.1246
	Stochastic conditioning [69]	0.8699	20.64	0.1106
	Interpolated denoising	0.8848	21.43	**0.0923**
GSO	Zero123 (no interp.)	0.8710	20.33	0.1029
	Standard auto-regression	0.8094	16.30	0.1801
	Interpolated conditions	0.7661	14.38	0.3427
	Interpolated outputs	0.8799	20.44	0.1659
	Stochastic conditioning [69]	0.8658	19.97	0.1119
	Interpolated denoising	**0.8820**	**20.73**	**0.0958**

Table 5. Quantitative comparison between our method to different auto-regressive variants. Note that the *Interpolated outputs* variant achieves the highest SSIM and PSNR values on the ABO dataset, but generates blurred images.

MonoSDF [81], our approach capture more details and generates smoother surfaces (note that [81] also relies on additional depth and normal estimations for its reconstruction whereas ours does not).

4.4. Ablations

Here, we study the effectiveness of our proposed interpolated denoising process by exploring various auto-regressive generation variants (in Tab. 5 and Fig. 7). Specifically, we investigate four variants of denoising: stan-
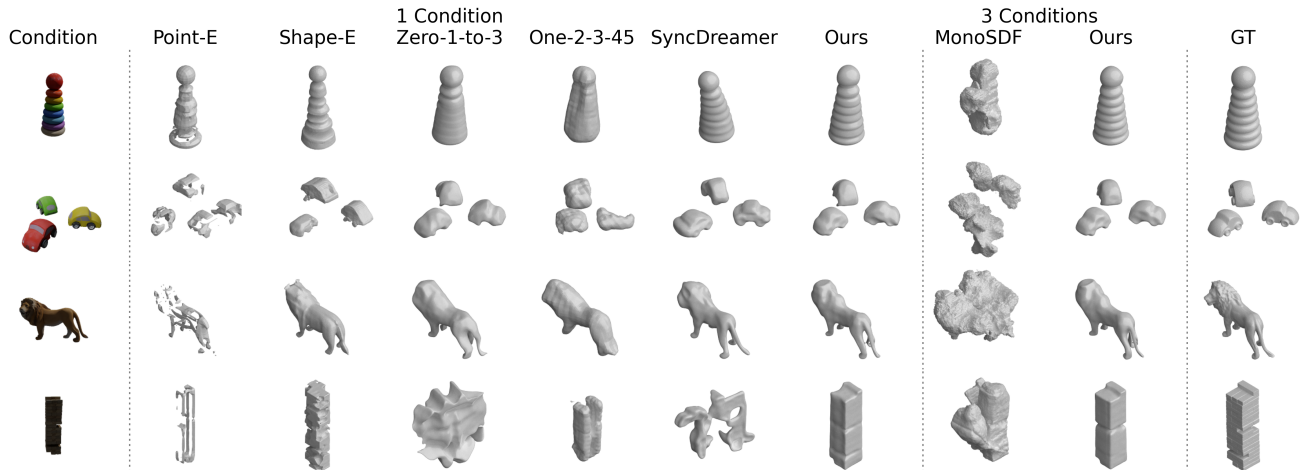

Figure 6. Qualitative results for single-view (1 condition image) and multi-view (3 condition images) 3D Reconstruction. Our method offers the most consistent results across a variety of different reconstructed shapes.

Figure 7. Qualitative comparison for different auto-regressive generations.

dard auto-regression, interpolated conditions, interpolated outputs, and stochastic conditioning which was proposed in [69].

Standard Auto-regression. One initial approach to auto-regression involves using the last generated view as the subsequent conditioning. However, this method exhibits bad generation quality, due to the accumulation of errors during the sequential generation process. As each subsequent view relies on the accuracy of the previous one, any inaccuracies or imperfections in earlier stages can compound, leading to a degradation in overall image quality. This limitation highlights the need for more sophisticated auto-regressive strategies to address the issue of error propagation and enhance the quality of generated views.

Interpolated Conditions and Interpolated Outputs. Interpolated Conditions and Interpolated Outputs are two straightforward approaches to introduce auto-regressive generation into an existing diffusion model. The former method involves interpolating feature embeddings from condition images and poses, while the latter interpolates the final image feature maps produced by the model. Despite

SSIM and PSNR metrics showing favorable results for Interpolated Outputs over others in Tab. 5, as illustrated in visual comparisons in Fig. 7 shows that it leads to blurring of the output views and this is corroborated by larger LPIPS distance.

Stochastic Conditioning. We also explore the application of the Stochastic Conditioning Sampler proposed by [69] to the Zero-1-to-3 model. We observe that Stochastic Conditioning fails to deliver the desired auto-regressive generation results; this may be attributed to the specific category on which the diffusion model used by Watson et al. [69] was trained, allowing it to handle plausible condition images more effectively. By contrast, Zero-1-to-3 [34] was trained on a cross-category dataset and designed for zero-shot reconstruction. Additionally, our evaluation data contains out-of-the-distribution data (*i.e.*, ABO [6] and GSO [9]).

5. Conclusion

In this work, we have developed ViewFusion, a novel algorithm that addresses the challenge of multi-view consistency in novel-view synthesis with diffusion models. Our approach circumvents the need for fine-tuning or additional modules by integrating an auto-regressive mechanism that incrementally refines view synthesis, utilizing the entire history of previously generated views. Our proposed diffusion interpolation technique extends the denoising process in pre-trained diffusion models from a single-view setting to a multi-view setting without training requirements. Empirical evidence underscores ViewFusion's capability to produce consistently high-quality views, and we achieve significant steps forward in novel view synthesis and 3D reconstruction applications.
