Abstract

We present a novel framework for controllable image restoration that can effectively restore multiple types and levels of degradation of a corrupted image. The proposed model, named TASNet, is automatically determined by our neural architecture search algorithm, which optimizes the efficiency-accuracy trade-off of the candidate model architectures. Specifically, we allow TASNet to share the early layers across different restoration tasks and adaptively adjust the remaining layers with respect to each task. The shared task-agnostic layers greatly improve the efficiency while the task-specific layers are optimized for restoration quality, and our search algorithm seeks for the best balance between the two. We also propose a new data sampling strategy to further improve the overall restoration performance. As a result, TASNet achieves significantly faster GPU latency and lower FLOPs compared to the existing state-of-the-art models, while also showing visually more pleasing outputs. The source code and pre-trained models are available at https://github.com/ghimhw/TASNet.

1. Introduction

Restoration of real-world corrupted images is a challenging problem since the types and the severity (or level) of degradation are unknown. Previous works on blind image super-resolution [4, 26] or blind deblurring [35, 14, 1] tackle this problem by learning to predict the unknown degradation kernel, and then using the predicted kernel to restore clean images. Recently, controllable image restoration has been gaining increased attention as alternative approaches. In this scenario, instead of accepting a single restored image given by the final model, users can control the output restoration to generate multiple images and choose the output image that best fits their preferences.

Early works on controllable image restoration (CIR) [15, 27, 31, 32] mostly consider a single type of degradation and modulate the levels of restoration. For instance, the denoising model from [15] allows continuous modulation of denoising a Gaussian noise with $\sigma = 15 \sim 75$. More recently, CResMD [16] proposed an extended framework that learns multiple types of degradation (Gaussian blur, Gaussian noise, and JPEG compression) jointly with a single network, so that users can interactively adjust not only the level but also the type of degradation. However, as more flexible control is enabled, two new challenges arise for the practical application of CIR models: 1) the high computation cost of generating multiple images to choose from, and 2) the difficulty of finding the true types and the levels of degradation, in which failing to do so may lead to significantly deteriorated outputs.

To alleviate these limitations, we present TASNet, a novel deep-learning-based CIR model that is optimized to achieve better visual quality and substantially reduced computational complexity. Figure 1 demonstrates a sample result.

Figure 1: An example of controllable image restoration. Our model generates visually more pleasing outputs while adjusting restoration levels with 3 times faster GPU latency and 95.7% reduced FLOPs compared to CResMD [16].
We also formulate the overall learning objective to be differentiable for efficient end-to-end training of our searching algorithm. This is why our algorithm allows channel-level selection for each layer as well as layer-wise decision of whether to share its parameters or not. Specifically, the proposed NAS algorithm selects: 1) the number of layers to share (task-agnostic part), 2) the important channels for the shared layers, and 3) the important channels for each task-specific layer, where these task-specific channel selection is adaptive for each task. We also formulate the overall learning objective to be differentiable for efficient end-to-end training of our searching framework, which results in the final TASNet. Moreover, we propose a new data sampling strategy to reduce the visual artifacts, which is empirically shown to be effective for cases when the task given by the user is very different from the true degradation of an input image.

Experimental results show that TASNet runs 3.7 times faster than the state-of-the-art CIR model on modern high-end GPUs with 95.7% FLOPs reduction when generating 4K images with 27 modulations. Also, the visual quality of the generated restoration using TASNet is much better than the previous approaches with significantly less artifacts.

Overall, our contributions can be summarized as follows:

- We present a novel neural network, named TASNet, for controllable image restoration (CIR) that remarkably improves the model efficiency and output image quality.
- We propose a supernetwork-based NAS algorithm that finds efficient CIR networks in a differentiable manner.
- We introduce a new data sampling strategy to improve the generated image quality in CIR problems.
- The proposed TASNet outperforms the state-of-the-art models in image quality and computation costs of FLOPs and CPU/GPU latency.

2. Related Work

2.1. Image restoration

Image restoration, including denoising, deblurring, super-resolution, and compression artifact removal, is a classical topic in computer vision which aims at restoring the original image from its degraded versions. Deep-learning-based image restoration networks [10, 11, 12, 18, 19, 21, 40, 42] have achieved breakthroughs in restoring accurate image details. While the conventional approaches specialize in dealing with a single degradation type, general image restoration aims to restore the corrupted image with multiple types of degradation. Notable approaches include learning a policy to determine a specialized restoration network for the input image [36, 37], or using an operation-wise attention module to produce the specialized feature maps w.r.t. each degradation type [29]. However, these approaches cannot control the diverse restoration levels for the input images, and sometimes generate overly smooth or sharpened outputs.

On the other hand, controllable image restoration is recently gaining interests from the computer vision research community, to control the output restoration of an image...
corrupted by unknown degradation. Existing works learn to control restoration levels for a single type of degradation [15, 27, 31, 32]. In particular, AdaFM [15], CFSNet [31], and Dynamic-Net [27] design their network architectures with tuning modules, which modulate the feature maps layer-wise [15] or block-wise [31, 27] with respect to the tasks of interest at test time. Instead, DNI [32] interpolates all parameters of the differently trained networks for modulation. For the general controllable image restoration, CResMD [16] controls restoration levels in multiple types of degradation with a block-wise tuning module. While the prior works may have provided good performance to control the restoration levels, they have solely focused on the image quality and do not consider computational efficiency. By contrast, using CResMD as the baseline, the proposed TASNet significantly reduces the computations and running time.

2.2. Efficient CNNs for image restoration

To make the image restoration models efficient with less computation cost, several novel architectures have been developed for diverse restoration tasks. The early works downscale the spatial resolution of the input image to reduce the computation costs of the convolution operations for denoising [41] and super-resolution [12]. More recently, CARN [3] presents a cascading residual block with multiple skip connections, leading to a fast and light-weight super-resolution network. For deblurring, a method using spatially variant deconvolution is proposed in [38] to achieve accurate performance with its efficient backbone network. Meanwhile, FALSR [8], ESRN [28], and FGNAS [17] adopt neural architecture search (NAS) algorithms for efficient super-resolution networks. Path-Restore [37] and AdaDSR [23] save computation costs via adaptive inference for general image restoration and super-resolution, respectively. Prior works also employ network quantization [9, 34] or pruning [13, 20, 24, 30, 39], but they are not task-adaptive.

On the other hand, we study the network acceleration approaches for controllable image restoration for the first time, especially when it requires a large number of inference passes per image. A neural architecture accelerated by our algorithm can be considered as a special instance of multi-task learning [7, 43], a network design paradigm that uses a shared network for multiple tasks or optimization. The main difference from the previous multi-task learning approaches is employing NAS for continuously varying tasks from an input image. Our search algorithm is a variant of supernetwork-based NAS methods [17, 22], which aim to find an efficient or performance-optimal network by pruning from a supernetwork. Our search process is performed over a search space of channels and shared layers across tasks, each combination of which provides a candidate network derived from a supernetwork.

3. Method

Controllable image restoration (or modulation) aims to control the restoration levels of a corrupted image. Following the CResMD setting, we formulate multi-dimensional restoration levels to be controllable. Formally, given $D$ number of degradation types, $t \in \mathbb{R}^D$ denotes a task vector, where $t_d \in [0,1]$ encodes the restoration level for the $d$-th degradation type. For instance, a task vector of $(1,0,0)$ for three degradation types (e.g., blur, noise, JPEG compression) indicates that the task requires the maximum level of deblurring but no denoising or compression artifact removal. During training, a training image pair (input and target) determines the corresponding values of task vector. At inference time, the task vector values are controlled by the users.

3.1. Efficient architecture design

Unknown degradation of real images demands interactive image restoration with adjustable restoration levels. In this scenario, a network for image modulation computes its operations multiple times for a single input image with different task vectors. Formally, the total computation cost for $M$ times of inferences is given by,

$$R_{\text{total}}(f, x, t) = \sum_{m=1}^{M} R(f, x, t_m),$$  \hspace{1cm} (1)$$

where $R(f, x, t_m)$ denotes FLOPs or latency to generate an output with the network architecture $f$, the input image $x$, and the $m$-th task vector $t_m$. Architectures used in CResMD and other previous works [15, 27, 31, 32] follow the computation cost of Equation (1), as outlined in Figure 2(a).

Our goal is to design a network architecture which is efficient under the aforementioned multiple -inference scenario. To this end, we propose TASNet that shares the feature map of early layers with the remaining task-specific architecture, as described in Figure 2(b). The task-agnostic shared layers facilitate feature reuse for repeated inferences from a single image. On the other hand, our task-specific architecture adaptively transforms itself to be efficient as it is difficult to find a single fixed network that is efficient for continuously varying restoration levels.

For TASNet, we reformulate Equation (1) and divide the network $f$ into the early layers $f^a$ and the remaining layers $f^b$. Then, the total computation cost becomes:

$$R_{\text{total}}(f, x, t) = \sum_{m=1}^{M} [R(f^a, x) + R(f^b, \tilde{x}, t_m)] \geq R(f^a, x) + \sum_{m=1}^{M} R(f^b_m, \tilde{x}, t_m),$$  \hspace{1cm} (2)$$

where $\tilde{x} = f^a(x)$ and $R(f^a, x)$ is the computation cost of a single inference for $f^a(x)$, and $f_m$ denotes the transformed
3.2. Search formulation

Overview. In order to find efficient TASNet architectures, we propose a supernetwork-based neural architecture search algorithm. Our search algorithm determines 1) the number of early layers that are shared across tasks, 2) the important channels for task-agnostic layers, and 3) the important channels for each task-specific layer, where the channels are selected from the supernetwork CResMD [16]. TASNet aims to minimize both restoration error and computation cost of Equation (2) via following rules, as illustrated in Figure 3:

- Learn task-specific channel importance \( z_{m,n}^s \).
- Learn task-agnostic channel importance \( z^a \).
- Share a feature map across tasks \( \phi_n = 1 \), when important channels are similar across tasks \( \eta_n = 1 \) and the feature map of its previous layer is shared \( \phi_{n-1} = 1 \).
- Maximize the number of shared layers (Equation (10)).
- Prune unimportant channels across tasks \( g(z_{n,c}^a) = 0 \) in shared feature maps \( \phi_n = 1 \).
- Adaptively select important channels \( g(z_{m,n,c}^s) = 1 \) to the task \( t_m \) in non-shared feature maps \( \phi_n = 0 \).

Channel selection. Variants of straight-through estimator [5] have been widely used for differentiable NAS approaches [33, 6]. To select or de-select each channel from the super network, channel selection virtually multiplies a binary value to the channel. Our straight-through estimator enables this process differentiable, formally given by,

\[
g(z) = \begin{cases} I[z > 0] & \text{if forward} \\ \text{sigmoid}(z) & \text{if backward} \end{cases}
\]

where \( z \in \mathbb{R} \), and \( I[\cdot] \) is an indicator function that returns 1 when its input is true (and 0 otherwise). We introduce two types of \( z \) which determine task-specific and task-agnostic channels, respectively, in the following.

Task-specific channel importance. To learn channel importance for a given task \( t_m \), we introduce architecture controller \( h \), formally given by,

\[
z_{m,n}^s = h_n(t_m),
\]

where \( z_{m,n,c}^s \in \mathbb{R} \) denotes the importance of \( c \)-th channel in the \( n \)-th feature map of the supernetwork \( h_n \) is the architecture controller, composed of few fully connected layers, for the \( n \)-th feature map.

Task-agnostic channel importance. To learn general channel importance across tasks, we simply average the values of the task-specific channel importance as follows:

\[
z_{n,c}^a = \frac{1}{M} \sum_{m=1}^{M} z_{m,n,c}^s.
\]

Channel importance similarity across tasks. To determine whether a feature map should be shared across tasks, we compute the agreement criterion via the similarity between selected channels from \( z^a \) and \( z^s \) as follows:

\[
\frac{1}{M} \sum_{m=1}^{M} \sum_{c=1}^{C} g(z_{m,n,c}^s) \cdot g(z_{m,n,c}^a) > \gamma \cdot \sum_{c=1}^{C} g(z_{n,c}^a),
\]

where \( \gamma \) is a threshold hyperparameter. Whether Equation (6) holds is represented by a boolean variable \( \eta_n \). If the equation
holds ($\eta_n = 1$), a large number of tasks have an agreement on
the channel importance for a given layer, and thus this
layer is likely to be shared across all tasks.

**Recursive layer sharing.** To facilitate feature reuse across
tasks, the shared layers need to be located together at the
initial stage of the network. To this end, the $n$-th feature map
is shared if the $n$-th and all previous feature maps satisfy the
agreement criterion on the position of pruning across tasks ($\eta_i = 1$), formally given by,

$$\phi_n = \begin{cases} 1 & \text{if } \eta_i = 1, \forall i = 1, 2, ..., n \\ 0 & \text{otherwise}, \end{cases}$$

(7)

where $\phi \in \mathbb{Z}_N^N$ denotes a decision variable, in which the
$n$-th element $\phi_n$ is 1 if the $n$-th feature map is task-agnostic.

**Objective function.** By using all equations above, we can
formulate the objective function with differentiable resource
regularization terms. Let $\mathcal{L}(\cdot, \cdot)$ denote a standard $\ell_1$ loss
function for image restoration tasks. The overall objective
function is formally given by,

$$\min_{\theta, \psi} \mathcal{L}(\theta, \psi) + \lambda_1 \cdot \mathcal{R}_1(\psi) + \lambda_2 \cdot \mathcal{R}_2(\psi),$$

(8)

where $\theta$ and $\psi$ are learnable parameters in the supernetwork
and architecture controller, respectively. The first resource
regularizer $\mathcal{R}_1(\cdot)$ penalizes FLOPs of currently searched
architectures by de-selecting channels, formally defined as:

$$\mathcal{R}_1(\psi) = \mathcal{R}_{\text{FLOPs}}(f^a, x) + \sum_{m=1}^{M} \mathcal{R}_{\text{FLOPs}}(f^s, \tilde{x}, t_m)$$

$$= 2 \sum_{n=1}^{N} K_n^2 H_n W_n \cdot \left[ \phi_n \cdot \sum_{c=1}^{C} g(z_{n,c}^a) \cdot \sum_{c=1}^{C} g(z_{n,c}^a) \right]$$

$$+ (1 - \phi_n) \cdot \sum_{m=1}^{M} \left[ \sum_{c=1}^{C} g(z_{m,c}^a) \cdot \sum_{c=1}^{C} g(z_{m,c}^a) \right],$$

(9)

where $K_n$ is the kernel size of convolution operation to
generate the $n$-th feature map, $H_n$ and $W_n$ are the height
and the width of the $n$-th feature map, respectively, and
$z_{n,c}^a$ and $z_{m,c}^a$ the channel of input images and are fixed
to be 1. The second regularizer $\mathcal{R}_2$ enforces the network to
maximize the number of the early shared layers by penalizing
the disagreement of selected channels across tasks as follows:

$$\mathcal{R}_2(\psi) = \sum_{n=1}^{N} \phi_{n-1} \cdot \sum_{c=1}^{C} \sum_{m=1}^{M} \left\| g(z_{m,n,c}^a) - g(z_{m,n,c}^c) \right\|_1,$$

(10)

where layer at $n = 0$ denotes an input image and $\phi_0 = 1$
since the input image is fixed over tasks. The hyperparameters $\lambda_1$ and $\lambda_2$ balance three terms.

#### 3.3. Data sampling strategy

**Degradation level vs. restoration level.** Previous works
train a network to restore the original image from the
degraded images with arbitrary degradation level (see Figure
4(a)). However, CIR algorithms should be able to restore
images to various extents to facilitate better user interaction
experience. Thus, we redefine a restoration level as a mapping
from more degraded images (input) to less degraded images
(relative GT) (see Figure 4(b)).

**Task vector with relative GT.** A task vector $t$ is a model
input that encodes restoration levels. In training, an input-GT
image pair (sampled with two different multi-dimensional
degradation levels) determines its task vector as follows:

$$t_d \equiv l_d^{in} - l_d^{gt},$$

(11)

where $l_d^{in} \in [0, 1]$ and $l_d^{gt} \in [0, 1]$ denote the levels of $d$-th
degradation type for the input and GT images, respectively.
We assume GT images are less degraded than input ($l_d^{in} \geq l_d^{gt}$). Each training image pair randomly selects the number
degradation types (single or multiple) and the granularity
of degradation levels (continuous or binary).

#### 4. Experiments

In this section, we present the experimental results and
comparisons between TASNet and CResMD in terms of
network computation cost and output image quality. Then,
we thoroughly analyze the effectiveness of our proposed
algorithm with the ablation studies. Implementation details
are described in the supplementary document.

#### 4.1. Dataset

In this work, we use DIV2K [2] dataset for training and
CBSD68 [25] dataset for testing, unless specified otherwise.
DIV2K consists of 800 clean 2K-resolution training images
and 100 validation images while CBSD68 consists of 68
clean HVGA-resolution test images. Following the degra-
dation setting in CResMD [16], to create degraded images,
we use three types of degradation: Gaussian blur, Gaussian

While displaying similar image restoration performance (as described in the next section), TASNet manages to reduce 95.7% FLOPs from CResMD and shows faster speed on all reported devices: \( \times 3.8 \) on a single-core CPU, \( \times 3.1 \) on a multi-core CPU, and \( \times 3.7 \) on a GPU, when generating 4K (3840x2160) images, compared with CResMD. Notably, TASNet only requires 0.07s to restore an HD (1280x720) image. We also observe that the latency difference between two models becomes small in the case of low-resolution images. As the input resolution decreases, the size of each feature map also decreases, reducing the benefit of selecting channels or shared layers to some extent.

4.3. Image quality comparison

Non-blind setting. Table 2 illustrates the quantitative image quality comparisons in a non-blind image restoration setting, where the degradation type and level of input images are known. This setting allows models to generate their best results with a single inference. The results demonstrate that the images restored by TASNet have lower PSNR than the images generated by CResMD but better NIQE, which means that TASNet in general restores sharper image details, as illustrated in Figure 5.

Blind setting. Controllable image restoration (CIR) algorithms aim to tackle a blind setting, in which the types and levels of degradation are unknown. CResMD [16] struggles to handle such challenging scenario, generating images with artifact (Figure 6) or over-smoothing effect (Figure 7) and restoring images unevenly across continuously varying restoration levels (Figure 8). Figure 6 presents images restored by algorithms that modulate an input image using different levels of deblurring when the input image is corrupted with a mixture of blur, noise, and compression degradation. Images restored by TASNet are shown to be less blurry (in fact, the outputs become sharper as deblurring level becomes higher), compared to CResMD that generates critical artifacts. An interesting observation is that other degradations
(noise and JPEG artifact) still remain in images deblurred by TASNet, implying that our algorithm manages to learn a disentangled restoration process for each restoration type and level. As observed in Figure 7, denoising by CResMD results in over-smooth images while TASNet maintains the overall contents and structures of input images. Figure 8 illustrates the restored images when varying the restoration (deblurring in this case) levels for identical degradation and restoration types. With the same amount of change in restoration levels, CResMD restores the degradation unevenly (the restoration quality changes negligibly or drastically), whereas TASNet generates images with smoothly-varying restoration quality.

**Restoration on real images.** Figure 9 displays the output images restored from real images with unknown degradation (downloaded from the internet). Similar to the synthetic examples, CResMD generates images with over-smooth effect or significant artifacts while TASNet successfully reduces the degradation of input images. For more restored output images, please refer to the supplementary document.

### 4.4. Ablation study

**The effectiveness of sharing layers in TASNet.** Table 3 studies the importance of task-agnostic layers in TASNet. In particular, we examine how the performance and computation cost change after disabling layer sharing, the resulting network from which is denoted as TSNet in the table. TASNet is observed to save the computation costs of TSNet by more than 5 times, owing to its shared layers that allow feature reuse and thus reducing the redundant computation for multiple inferences. Regardless, TSNet greatly reduces the computation cost of CResMD, suggesting the effectiveness of the task-specific layers that adaptively select important channels. In stark contrast, conventional channel pruning approaches do not change their architectures w.r.t. the task.

To further emphasize the effectiveness of TASNet, Figure 11 shows the computation cost of TSNet and TASNet across various tasks with multiple number (4) of inferences for each image of HVGA resolution (481×321). Task-specific layers in both networks tend to require more channels for higher restoration levels, which translate to more difficult restoration problems. Task-agnostic layer in
TASNet is computed only once for each input image and hence requires a substantially smaller amount of computation from the second pass. Although TASNet requires higher computation cost than TSNet for the first inference, the overhead becomes negligible during multiple inferences.

**Comparison to naïve shared networks.** Table 4 shows the comparisons between the variations of CResMD with a different number of early shared layers that is manually determined. For fair comparisons in terms of performance, all models in the table are trained with absolute GT. TASNet-A has the same network architecture as TASNet, but is trained with absolute GT. TASNet-A reduces the computation cost of CResMD to $\frac{1}{9}$ by sharing 62% of the layers while maintaining the similar PSNR performance.

**Image restoration quality analysis.** To study the effectiveness of the proposed data sampling strategy and the TASNet architecture, Figure 10 presents quantitative restoration performance of three major failure cases in CIR when the controlled restoration levels differ from the actual types and levels of degradation in a corrupted image. The results of CResMD trained with relative GT generates less artifacts and evenly modulated outputs, validating the capability of the proposed data sampling to improve image restoration quality. Also, TASNet achieves higher PSNR (over 3 dB compared to CResMD) in denoising without over-smoothing (Figure 7 and 10(c)), alluding to the effectiveness of the shared layers in providing better image quality.

Figure 11: Computation cost comparisons across restoration levels. The higher restoration levels demand more computation costs for TS layers. TASNet is efficient for multiple inferences, as a result of reusing the feature map of TA layers across tasks. Each graph presents computation costs of removing blur (upper left), noise (upper right), and joint degradation of blur and noise (lower left). A task vector $(\ldots)$ denotes the levels of (Deblur, Denoise, Dejpeg).

5. **Conclusion**

We propose a novel neural architecture search algorithm to find efficient networks for controllable image restoration (or image modulation). In particular, the proposed algorithm searches for a network with task-agnostic and task-specific layers, referred to as TASNet, by determining the number of layers and channels to share across tasks and adaptively selecting channels in non-shared feature maps. We formulate all learning objectives in a differentiable manner and perform the architecture search in an end-to-end manner. The shared layers facilitate feature reuse that pushes the network efficiency further for controllable image restoration that requires a several number of inferences. Together with the proposed new data sampling strategy, not only does TASNet reduce the network computation costs of the state-of-the-art network greatly but also provides the better image quality.
