Supplementary Details: This document is organized as follows. Sections S1 and S2 contain additional analysis and visualization of various aspects of our localization and restoration networks. Experiments on performing multi-task learning using SPAIR are provided in Section S3. The document concludes with Section S4 providing additional qualitative results and comparisons on various benchmark datasets for all four tasks.

S1. Model Analysis

S1.1. Effect of Spatially-Selective Processing

We perform a few analytical experiments to verify the effectiveness of spatially-selective processing. We vary the threshold (for intensity change to be classified as significant distortion) and calculate the PSNR on thus obtained degraded and non-degraded regions separately. Owing to the adaptiveness of our approach and specialized modules for the current task, we achieve better restoration results for the regions with significant corruption (Fig. S2). This behavior is generally expected from better restoration network design. Interestingly, we observed that, for regions with negligible amount of degradation (non-degraded regions for very low threshold), the input image itself is sufficiently good (Fig. S2). Due to generic processing, most of the previous methods are unable to reconstruct those regions accurately (i.e. they corrupt the background pixels) and result in poor PSNR even in the simplest of regions.

Next, we visualize the error-maps (the difference between degraded and ground-truth image) for the non-degraded regions in Figs. S3 (RainStreak) and Figs. S4 (Raindrop). As we can observe, our method results in the least amount of reconstruction error. The improvement over existing methods in the non-degraded areas shows that SPAIR causes least amount of changes in the non-degraded pixels. Improved restoration in degraded regions is attributed to modules specifically processing the degraded regions. Our method preserves input details which are uncorrupted and is able to improve the quality of the restoration of affected regions.

S1.2. Effect of SNL

The SNL module processes only degraded pixels by non-locally aggregating information selectively from the non-degraded regions. Attention over regions filtered by mask selects only the most relevant features, improving performance. In SNL’s first step, each pixel/position receives weighed aggregation of features lying only in horizontal and vertical directions. Serially performing two such steps expands the span to all pixels. For a direction \( d \) and degraded location \((i,j)\), Eq.3 generates an attention map using \( F_{i,j}^d \) (features from non-degraded locations). Next, Eq.4 performs a weighted sum to gather contextual information from uncorrupted positions based on their utility (measured using the attention maps). Instead of operating with a \( N^2 \times N^2 \) attention matrix (as in [59]), decomposition into processing sparse pixels in 4 directions separately reduces complexity to \( O(N\sqrt{N}) \), making SNL effective and memory efficient.

S2. Analysis on Distortion Localization Network (\( Net_L \))

We have visualized predicted distortion-mask along with the ground truth distortion-mask in Fig. S1. The close resemblance of the predicted and ground truth degradation maps shows the effectiveness of \( Net_L \).

Figure S1. Visualization of degradation mask for different tasks. First, second, third row describes input image, ground-truth mask,predicted mask respectively
S2.1. Supervised vs unsupervised learning

We choose to train $Net_L$ in a supervised fashion, since accurate pixel-level distortion estimation is of key importance in restoration.

S2.2. Impact of Accuracy of $Net_L$

Note that, compared to the ground truth mask, there will inevitably be some errors in the predicted one. Although our proposed modules in the decoder leverage the extra guidance from the predicted mask, as there are standard convolution layers too in the decoder and the restoration network is trained with the predicted mask itself, errors in very few pixels of the predicted mask do not adversely affect the final restoration output. $Net_L$ classifies some regions as non-degraded, while slight intensity distortions may well be present in those areas. Nonetheless, restoration of such distortions is easy and this is achieved through the few non-sparse layers in our network.

We conduct the following experiment to show that at convergence, final performance of $Net_R$ is not very sensitive to small error in the prediction of $Net_L$. The variation of $Net_R$’s performance with respect to $Net_L$’s cross-entropy loss is shown in Table S1.

Table S1. Influence of the accuracy of $Net_L$ on performance of SPAIR for raindrop removal evaluated using AGAN Dataset [13].

S2.3. Relationship between mask and blur

We performed the suggested analysis using optical flow, which is a good approximation to motion blur (as demonstrated in [10]), Fig. S2.3 shows optical flow for two consecutive sharp frames (from dataset [35]), indicating spatial distribution of blur magnitude. The blurred image (available in [35]) corresponding to the sharp frame is passed through $Net_L$ to obtain the distortion mask. High spatial correlation can be observed, establishing the utility of our mask. Dynamic objects or regions closer to the camera usually contain highly blurred texture, and the same regions are revealed in the mask $\mathcal{M}$. Note that textureless pixels (eg. in clothes, skin) incur minimal distortions from blur and hence are absent in $\mathcal{M}$.

S2.4. Comparison with AGAN [13]

Balance error rate [7] scores (with best threshold) for AGAN [13] and $Net_L$ are 8.15 and 4.58, justifying the utility of $Net_L$.

S2.5. Choice of loss

Even through advanced loss functions/training optimizers would offer benefits complementary to our architecture, we used L1 loss for fair comparison of SPAIR with all competing restoration methods[44,51,56]. L1 error value at $\mathcal{M} = 0$ is often smaller than at $\mathcal{M} = 1$, making it predominantly a restoration loss. Nonetheless, there is potential for further performance improvements by incorporating perceptual loss and confidence-driven reconstruction loss specifically on the degraded regions.

S3. Exploring Multi-Task Learning

We also explore an additional benefit of our design. Since our architecture design does not change across restoration tasks, it opens venues for multi-task learning. We perform experiments on jointly learning two restoration tasks. Among the 4 spatially-varying degradations we consider in this paper, we choose to address Rain-Streaks and RainDrops jointly, as they are closely related to each other and generally occur in similar environments. We explore the possibility of obtaining a single trained model which can remove raindrops as well as rainstreaks from a given test image. We train SPAIR jointly on the datasets of two tasks: Mixed RainStreak Dataset [9] (used in Table 1 of main paper) and RainDrop Dataset [13] (used in Table 3 of main paper). After training jointly on the two tasks, we evaluate the model on the two benchmarks and compare against existing task specific methods. We also include the recent multi-task restoration model OWAN [17] as a baseline and train it in the same setting as SPAIR.

Specifically, we train our model on 14573 clean-degraded image pairs gathered from rain-streak datasets [4, 11, 22, 24, 25] and the raindrop dataset [13]. With this single trained model (referred to as SPAIR (Joint)), we perform evaluation on different test sets, including Rain100H [22], Rain100L [22], Test100 [25], Test2800 [4], Test1200 [24] and AGAN [13]. The results on the two tasks are reported in Tables S2 and S3. It is evident that SPAIR (Joint) is the first model in literature to achieve state-of-the-art results on Rain-Streak and RainDrop removal tasks, without additional training.

S4. Additional qualitative comparisons

Rain-Streaks: Figs. S5, S6 show additional qualitative results and comparisons state-of-the-art methods on Rain100H Dataset (Table 2 of main paper). Existing methods suffer from visible rain streaks or texture-smearing
Figure S2. Comparison with baseline methods using PSNR scores in degraded and non-degraded regions for two tasks: rainstreak removal and raindrop removal. (Best viewed in color).

Table S2. Image deraining results using SPAIR trained jointly for Rain-Streak and Raindrop removal tasks. Best and second best scores are highlighted and underlined. SPAIR significantly outperforms baselines methods in both settings: Single task and Joint task learning.

along rain direction. In comparison, our results are visually more pleasing, while being faithful to the ground-truth image. Fig. S7 contains comparisons of all methods trained on the combined RainStreak Dataset (Table 1 of main paper).
It is evident that few rain streaks remain visible and background remains unclear in the results of all existing methods while our approach generates satisfactory deraining results.

**Raindrop:** We show additional results on the test-set of AGAN dataset in Figs. S8,S9,S10. We also include comparisons on a real-world image in Fig. S11. Visually, we can observe significant improvement over prior works.

**Shadow Removal:** Fig. S12 provides additional qualitative comparisons on shadow removal showing that most existing approaches produce shadow boundaries or color inconsistencies. In contrast, SPAIR has minimal artifacts in the shadow boundaries, outperforming the baselines both qualitatively and quantitatively.

**Motion Blur:** While the GoPro and HIDE datasets are generated by averaging consecutive frames of real high frame-rate videos, the blurred images in RealBlur-J dataset are captured in real-world conditions. In Fig. S13 we provide comparisons of our results with the best results from [16]. In Figs. S14-S18, we provide additional results and visual comparisons of our architectures with competing meth-
