Abstract

The field of explainable AI (XAI) has quickly become a thriving and prolific community. However, a silent, recurrent and acknowledged issue in this area is the lack of consensus regarding its terminology. In particular, each new contribution seems to rely on its own (and often intuitive) version of terms like “explanation” and “interpretation”. Such disarray encumbers the consolidation of advances in the field towards the fulfillment of scientific and regulatory demands e.g., when comparing methods or establishing their compliance w.r.t. biases and fairness constraints. We propose a theoretical framework that not only provides concrete definitions for these terms, but it also outlines all steps necessary to produce explanations and interpretations. The framework also allows for existing contributions to be re-contextualized such that their scope can be measured, thus making them comparable to other methods. We show that this framework is compliant with desiderata on explanations, on interpretability and on evaluation metrics. We present a use-case showing how the framework can be used to compare LIME, SHAP and MDNet, establishing their advantages and shortcomings. Finally, we discuss relevant trends in XAI as well as recommendations for future work, all from the standpoint of our framework.

1. Introduction

The growing demand for explainable methods in artificial intelligence (a.k.a. eXplainable AI or XAI) has recently caused a large influx of research on the subject [3]. However, proposed solutions have spanned into multiple niches simply because they are based on different definitions for terms like “explanation” or “interpretation”. An increasing number of contributions rely on their own, and often intuitive notions of such terms—a phenomenon dubbed “the inmates running the asylum”–which eventually leads to failure to provide satisfactory explanations [26].

This self-reliance in the goal’s definition has caused confusion in the machine learning community, as there is no agreed upon standard which can be used to judge whether a particular model can be deemed “explainable” or not. This issue has been accentuated by what the term “explanation” refers to in the context of AI. Is it an approximation of a complex model [1, 24], an assignment of causal responsibility [25] or a set of human intelligible features contributing to a model’s prediction [27]? To make matters worse, a variety of circular definitions for “explanation” can be found, alluding to further concepts like “interpretation” and “understanding” which are, in turn, left undefined.

Early work, stemming mostly from philosophy, gravitated around the idea of “explanation” as a perennial carrier of causal information [20, 16]. More recently, we find literature that concentrates on the ethos of XAI with a focus on applications in ML. Most acknowledge the epistemological leniency when talking about “explanations” and terms alike [27, 21, 39]. A recurring motif from this literature is also to define “explanations” or “interpretations” as an agglomeration of different, more specific terms like confidence, transparency and trust [39, 9, 12]. Some work focuses on classifying the requirements that an explainable system should meet [39, 21] or the kind of evaluations through which a model can be deemed explainable [21, 12]. This lack of consensus has resulted in research that, albeit exciting, ends up tackling different problems, making it impossible to list and compare literature solely based on what has been called “explanation” [6, 21].

In order to measure and compare progress in the field of XAI, we argue that a unified foundation is vital, and that such foundation starts with an adequate definition of the field’s terminology. In particular, we propose a framework based around atomic notions of “explanation”, and “interpretation” in the context of AI (with a special focus on ML and applications in computer vision). We show how further
Concepts mentioned in the literature can be rephrased in relation to our proposed definition of “explanation” and “interpretation”, facilitating the comparison of methods claiming to be explainable.

## 2. Context and definitions

In order to lay down a sound and inclusive foundation, we start by looking at core aspects that most research in XAI share, but also at what makes them incompatible. What counts as an atomic notion and what is treated as a system, has been the prerogative of each scientific contribution. This has been in part acceptable, given how under-specified modern ML tasks are [22, 10]. Starting from an intuitive idea of object classification, we already assume and accept the interaction of signs, objects and interpreters from semiotic theory [35]. These requirements get further reduced to low-level mathematical primitives e.g., the notion of a “chicken” gets represented as a set of points $x \in \mathbb{R}^d$, which get further simplified as tensors of bytes in the range $[0, 255]$.

In turn, XAI is essentially searching for evidence about non-functional requirements of the high-level task (e.g., whether a higher relevance score is being attributed to the area where a target object is) within the low-level primitives such as tensors, probabilities, and model parameters (Figure 1). The way we accept mathematical distributions as evidence for the presence (or absence) of an object in an image follows a well-defined mapping from high-level ideas to low-level primitives. Now, in the absence of well-established mappings between the task’s non-functional properties and its corresponding low-level primitives, we are obliged to define one explicitly.

To that end, we propose a framework to establish mappings for non-functional properties, such that existing work is covered by it while providing the required rigor to serve as a vehicle for scientific discussion. We begin by identifying two fundamental characteristics that such a framework must have:

### 1. Commensurable: in order to fairly compare two different methods, common measures need to exist. A common vocabulary is therefore required, upon which these metrics can operate. In particular, what counts as an “explanation” and what is “interpretation” needs to be agreed upon beforehand.

### 2. Universal: a generic workflow has to exist, defining the context that identifies atomic primitives, and operations on those primitives. Comparisons between primitives and operations are possible as long as the context in which they are being compared remains the same.

We begin by looking at general notions and definitions for the terms “explanation” and “interpretation” as a basis for a refined characterization of said terms in the context of XAI. Moreover, we will identify the minimal requirements for defining a context and therefore, for bounding the scope of explanations and interpretations.

### 2.1. Towards commensurable explainability: a common vocabulary

Most definitions treat “explanation” and “interpretation” in a similar fashion, sometimes even as synonyms. However, there are subtle but fundamental differences that allow some initial distinction to be drawn between them. First, we need to ask what kind of semantic entity an explanation is: is it an action, an outcome, a process or an object? For most textbook definitions (see Table 2), explanations are methods that probe for said requirements. Interpretations are mappings from low- to the high-level domain.
facts in the form of low-level mathematical primitives used to build the models themselves: support vector machines have a decision boundary equation, support vector coordinates, etc. A Neural Network has values for each parameter, equations governing how they connect with each other, a value of the cost function when computed on a particular input, etc. All of these are concrete, undisputed facts (assuming there are no bugs) that are suitable explanandum.

In a simplified, more intuitive form, a first definition of “explanation” can be formulated as follows:

An explanation is the process of describing one or more facts.

The third aspect of an explanation deals with its purpose. Ideally, the output of the explanation (i.e., the explanans) exposes patterns or statistics that were not evident before. For example, overlaying the gradients of an image classifier w.r.t. an input sample $\frac{\partial L(f(x), y)}{\partial x}$ can locate areas that are more sensitive to changes in the input. Once more, resorting to textbook definitions we see that most of them mention “making something understandable, clear, comprehensible” as the goal of an “explanation”. In other words, the purpose of an explanation is to enable (human) understanding. Explanations are therefore bound to describe facts in a way that ultimately enable (human) understanding. At this point, we can think of what consumers of explanations (i.e., explainees) need to understand: on the one hand, there are characteristics of the fact being described (e.g., location of the magnitude and sign of a gradient w.r.t. an input sample) which may help one understand what the gradient is. On the other hand, there are some characteristics of the described fact in relation to other high-level phenomena e.g., how a high gradient value relates to a latent relevant feature.

---

Assuming that the explane’s mental model is otherwise equipped with the necessary knowledge to understand this concept.
With this in mind, we arrive at a revised definition for “explanation”:

An explanation is the process of describing one or more facts, such that it facilitates the understanding of aspects related to said facts (by a human consumer).

In order to constrain the many ways a description can be interpreted, a contract must be introduced detailing the valid meanings that can be extracted from that description. In other words, there should be an agreement on how to read the symbols of a description e.g., which colors on a heatmap mean high or low values. Such agreement anchors or assigns meaning to a primitive entity (in our case, an explanans).

Referring back to textbook definitions for “interpretation”, we see how most of them rely on the term “explanation”, and thus leading to an inexorable circular definition. The one remaining exception follows the philosophical origin of the word and already lays out the requirements of a contract by defining an “assignment of meaning”. In fact, the conveyance of meaning is common to all entries, in one way or another. We go along these lines to sketch the definition of interpretation in XAI as follows:

Interpretation is the assignment of meaning (to an explanation).

For ML, the assigned meaning refers to notions of the high-level task for which the explanans is provided as evidence. An interpretation is therefore bridging the gap between underspecified non-functional requirements of the original task and its representation in formal, low-level primitives (e.g., high Shapley values for pixels on a chicken’s beak indicate its correct detection and relation to the class “chicken”).

In order for an explanation to fulfill its goal (facilitate understanding), the terminology and symbols known to the explanaee i.e., the consumer of the explanation, have to match those used by the explainer i.e., the proponent of the explanation, when assigning meaning to an explanation. In other words, the complexity (otherwise known as parsimony) of the interpretation should not be greater than the explanaee’s capabilities to fathom its meaning [29, 34]. Sometimes, there are no fundamental reasons to prefer one interpretation over another (e.g., make red represent high values instead of blue or white) as long as one is agreed upon.

Even if the methods to explain (or the agreements to interpret) vary, the process of understanding will always be supported by the same mechanism: description of facts followed by the assignment of meaning for the description itself. While the meaning being assigned can be contested (e.g., as part of the scientific process where one seeks to falsify a statement) the process of assignment cannot.

2.2. Universal context for XAI methods: the what, the how and the why

One of the main aims of equipping ML models with explanation capabilities is to contest previous beliefs w.r.t. a particular prediction by constraining an otherwise undetermined problem [22]. So far, we have already constrained two core definitions in XAI, in an effort to define a unified language that allows us to engage in scientific discussion. Said terminology still needs to fit into a more generic, procedural framework where novel and existing contributions can be placed and thus, compared.

Explanations and interpretations are ultimately aimed at answering questions arising from the underlying process (i.e., the ML model) that issued a prediction. These questions, in their more generic form, correspond to variants of what, how or why queries. Hence, our interest lies in defining a framework that addresses these questions when defining novel explanations and interpretations. In fact, we show that both terms are central for answering all three questions. We describe the scope of the aforementioned questions, and the role that explanations and interpretations both play when answering them.

The what defines the domains in which explanations operate. As defined in section 2.1, we find that explanations, as processes, take in elements of a particular source domain, and output descriptions that exist in a target domain. This notion of “translation” between two domains has been recently promoted [13] although the terminology differs with the one proposed in this work. In mathematics, whenever a function is defined, it is first expressed in terms of the domain and co-domain where the function projects values into e.g., $f : \mathbb{R}^{d_x} \rightarrow \mathbb{R}^{d_y}$. Similarly, an explanation method should explicitly state what is being used as input and what is being produced as output. Ideally, the output of the explanation (explanans) should be defined in terms of low-level primitives that are as factually true as the input (e.g., intermediate features, support vectors, gradients). Note that, while inputs in the source domain are limited by the model being explained, the target domain depends on the explanation method, where options are virtually unlimited².

Defining how something is being done can be addressed from two levels of abstraction. First, at the system-level, there is the question of how the model arrives at a prediction. Second, there is the issue of how the explanans is produced. In other words, what are the details behind the process that transforms between domains defined by the what, and used by the explanation. The former is precisely the kind of inquiry that XAI methods try to answer and therefore, they cannot be included in our frame-

²Practical constraints arise from the cognitive limitations of human minds (e.g., the inability to imagine a tesseract).
work. Instead, this kind of how questions will be answered through methods that rely on it\(^3\). The latter on the other hand, deals with the context of explanations and their answer is essentially reduced to the explanation method itself. Simply put, the answer of how the explanandum is mapped to an explanans is defined by the explanation method.

As most XAI literature is devoted to the development of explanation methods (e.g., computation of relevance values [4, 36], mapping of high-level conceptual constructs in intermediate activations [5, 17]), the how is almost always thoroughly defined. This has already nurtured insightful debates on whether linear approximations of the original model [24] or even other black-boxes [1] can be considered appropriate explanation methods [31, 33].

Together, the what and the how already constrain the scope in which explanations are valid. The one remaining aspect is the context in which an explanation is interpreted. An explanans is, by itself, only relevant within the target domain defined by the explanation. It is the interpretation (of the explanans) which will map the low-level representations into a high-level domain where expectations regarding non-functional requirements can be validated or contested. Consider the following interpretation: “the result of an argmax operation on the logits of a neural network corresponds to the predicted class”. The high-level action of predicting a class has been mapped to an argmax operation over a vector. Based on this interpretation of the argmax operation, users of neural networks can either accept this notion to gather results, or find shortcomings and propose alternative ways of fulfilling the requirement of a model to predict classes (e.g., through the refinement of the prediction through a hierarchical exclusion graph [11]). The same principle can be applied to explanans and non-functional requirements.

Asking why something happens, inescapably relates back to causal effects. While these kind of relationships are among the most useful to discover (as it allows for more control over the effect by adjusting the cause), other non-causal relationships remain valuable in the toolset of explainability. Finding out that a model is unfair, without knowing what the cause of it is, can already be helpful in high-stake scenarios (e.g., by preventing its use). We say that the why relates to the nature of an interpretation. In short, if the interpretation bares a causal meaning, then the why is being defined by the causal link. If the meaning is limited to a correlation, the why is left out of the scope of that particular interpretation. Note that, if the explanation method is already based on causal theory [23, 8], the assigned meaning (i.e., the link between the explanans and the high-level (non-)functional requirement) will be more direct and therefore, more likely to withstand scientific scrutiny. The why is therefore not mandatory in explanations generated by XAI methods. In any case, the explanation’s context can and should be defined, be it causal or based solely on correlations. Proponents of XAI methods are responsible for clearly stating the context in which their explanations can be interpreted.

3. On the completeness of the XAI framework

We show that our proposed framework complies with concepts and desiderata related to explanations and explainable models. In particular, those that have been defined by Alvarez-Melis and Jaakkola [2], and Miller [25]. Furthermore, we discuss evaluation metrics for XAI methods (as defined by Doshi-Velez and Kim [12]) and how they also fit
within our framework.

For Alvarez-Melis and Jaakkola [2], there are three characteristics that explanations need to meet: fidelity, diversity and grounding. Fidelity alludes to the preservation of relevant information; diversity states that only a small number of related and non-overlapping concepts should be used by the explanation, while grounding calls for said concepts to be human-understandable. In our proposed framework, fidelity is guaranteed as explanations are defined as mechanisms to describe or map inputs that are axiomatically valid using a well-defined function. Although defining an absolute number of concepts can be rather subjective, diversity is possible by allowing a designer of explanations to purposefully focus on a few concepts on the input or output of the explanation. Grounding is essentially addressed by the interpretation, as it is the mapping from a low-level primitive to a high-level, human-understandable realm of a non-functional requirement. Moreover, explanations require the production of artifacts specifically targeted at enabling human understanding.

Miller [25] has highlighted several aspects of explanations that the XAI community has been mostly unaware of: the social, contrastive and selective nature of explanations, and the irrelevance of probabilities when providing an explanation. When defining the domain and co-domain of an explanation, there are several ways by which contrastive explanations can be offered: either several explanandum can be processed, and their explanans compared, or the explanation method itself expects multiple input pairs (possibly producing output pairs too). Employing causal methods as explanations will inevitably encode counterfactual information (e.g., the result of applying a do-operator) enabling a comparison with respect to the observed data. Selective explanations closely relate to the concept of diversity from Alvarez-Melis and Jaakkola [2]. The irrelevance of probabilities mainly states that the best explanation for the average case may not be the best explanation for a particular explainee. While true in some cases, the usefulness of tailored explanations is contingent on the use-case (as providing different explanations for two identical cases may violate fairness constraints). Nonetheless, our framework does not preclude an explanation from doing so if the use-case calls for it. Finally, the social aspect of explanations is reflected by its very definition, as the purpose of explanations is to “enable human understanding”. Furthermore, interpretations are mappings from low-level to high-level requirements, precisely to make an explanans consumable by humans.

General guidelines for measuring explanations (or better said, their outputs) have been proposed in [12]. These are based on three kinds of evaluations depending on the scope of the application (from generic to specific) and they revolve around the involvement of automatic proxy-tasks, non-expert humans, or domain experts. The use of automated tasks would be amenable primarily to explanations, as they already live in the realm of data structures and mathematical primitives. Evaluations that involve humans will thus be better suited for the interpretations, as mappings to a high-level domain, where the non-functional requirements originate, ultimately affect human understanding (therefore impacting trust, confidence, etc).

A fitting example of quantifiable criteria for explanations can be found in the aforementioned work by Alvarez-Melis and Jaakkola [2]. They propose three, arguably generic characteristics that their proposed explanations should meet, namely explicitness, faithfulness and stability. We see that such properties also refer to aspects defined in our framework: explicitness or “how understandable are the explanations” establishes how clear the interpretation of their provided explanans (in their case, a selection of prototypes describing an expected latent feature) is. Faithfulness or the “true relevance of selected features” is directly addressing the quality of an explanans via counterfactual analysis (i.e., had the selected feature not been there, would the prediction suffer any change?). Finally, stability measures consistency of the explanation for similar inputs. As part of the particular classification problem they work on, said property deals with an expected local Lipschitz continuity which guarantees that similar input samples will yield a similar explanans.

We see how our proposed framework offers a comprehensive language that not only aligns and encompasses previously defined desiderata regarding XAI, but also allows the identification of common ground between a wide array of concepts related to the field.

4. Understanding the state of XAI under our proposed framework

The proposed explanation framework helps establishing unambiguous and commensurable relations across all kinds of XAI contributions. We demonstrate the broad applicability of our framework by re-contextualizing three popular methods, LIME, SHAP and MDNet, showing how and where they compare, while also revealing some of the gaps and complementary properties between them.

Additive feature attribution methods like LIME [30] and SHAP [24] are two frequently used XAI techniques today. Both were introduced as model-agnostic methods, aiming at approximating the behavior of complex models, all without requiring access to their internal variables. On the other hand, MDNet [40] was proposed as an “interpretable medical image network” for diagnosis of bladder cancer through the generation of textual diagnosis along with word-wise attention maps. At first glance, establishing a degree of commensurability (as defined in section 2.1) is not straightforward, especially when dealing with methods that operate on

vastly different domains or whose explanations tackle different sets of non-functional requirements such as MDNet’s and LIME’s. However, by defining the different elements of all three methods in terms of our proposed framework, it becomes possible to establish comparisons and draw limitations with respect to one another. We discuss said elements in the remaining of this section. For a summary of the ensuing discussion, please refer to Table 3.

4.1. Source domain:

The explanandum of LIME and SHAP comprises the prediction of the target model, as well as an input sample. The target model is treated as a black-box, and typically deals with low-dimensional inputs. Meanwhile, MDNet’s textual and visual explanations are derived from an input sample, and from high-dimensional latent variables found within the target model. LIME and SHAP represent the target model’s low-level internal processes mainly through counterfactual analysis, while methods exposed to the model’s internals can examine the flow, translation and attribution of information as it traverses the model, serving as more direct evidence of a model’s decision process. In fact, it has been shown that limiting access to the target model’s internal representations makes the creation of adversarial attacks possible, compromising the reliability of the explanation [33]. In other words, it is not enough to rely only on the input domain (of the target model) as the explanandum.

4.2. Target domain:

The outputs of both LIME and SHAP consist of the weight values from linear surrogate models that are mapped to their corresponding input region (visualized as heatmaps). Instead, MDNet’s explanans is composed of a sequence of one-hot encoded words from the language model, where each word is paired with a $14 \times 14$ weight matrix that is spatially mapped to the input image (also visualized as a heatmap). The combination of generated text supported by word-wise attribution maps provides a traceable structure from the model’s input to the weight matrix. While LIME and SHAP provide explanans that share some of the output space with MDNet’s, the relation they bare with any internal representation of the target model is not as traceable.

4.3. How:

LIME and SHAP follow similar explanation strategies characterized by continuously perturbing and evaluating input samples via the target model; results are subsequently approximated through a surrogate linear model. SHAP poses additional constrains to the surrogate’s optimization and slightly differs in its sampling scheme. MDNet can be described as a two-stage process: an image feature extraction followed by a concurrent generation of a sensitivity map (originally called “explanation”) and textual diagnosis. Both the explanation and classification components of MDNet are trained simultaneously in an end-to-end fashion. The language model is trained using diagnosis texts as the supervisory signal, fulfilling one of its functional requirements. The word-wise attention module learns a set of sensitivity weights with additional constrains on diagnostic labels serving as indirect supervision.

---

4 Most local explanation methods rely on individual samples from the model’s input space as input for the explanation too. Non-local methods like TCAV [17] or S2SNet [28] rely on a group of samples or even a representative sample of the input space.
4.4. Why:

Given all structural and low-level components of the explanations under scrutiny, as described by the what and the how, we now turn to the interpretation of such primitives. The first observation is that none of the aforementioned methods provide interpretations of causal nature. LIME and SHAP cannot provide interpretations grounded in causality due to issues related to off-manifold sampling [14] and the non-excludable inaccuracy when relying on proxy models [31]. Nevertheless, there are non-causal interpretations worth examining.

The weight values derived from LIME’s proxy models are interpreted as “influence values”. These values convey the relevance of individual input features w.r.t. the prediction of the target model. A small caveat to this interpretation is its limited validity, which applies only to the local neighbourhood around the original input sample. SHAP’s explanans, despite baring evident similarities with LIME’s, allows the generation of additional global explanans through an accumulation of statistics from multiple local explanations. Furthermore, the notion of feature attribution (i.e., how much the value of each input feature has influenced the model’s prediction) inherits the properties of Shapely values. In this case, values are interpreted as payouts to individual features, reflecting how much they contributed to the model’s prediction, relative to the remaining input features. MDNet’s visual explanations are interpreted as the model’s attention w.r.t. a region within the input image while the textual-diagnosis generates a word. In this case, we see how MDNet defines explanans as part of the model’s output and not as a separate process, tying predictions and explanans together. The correspondence between feature attribution on the image domain and the sensitivity w.r.t. generated text comes from additional annotations available for the text. The assumption is that latent representations of MDNet align features of image regions and text in a way that is meaningful to humans. The link between the intuitive notion of “attention” and its implementation in one of MDNet’s modules, has been recently contested [15, 38], underlining any causal relation drawn from it.

5. Conclusions

To address the growing heterogeneity and lack of agreement on what constitutes an explainable or interpretable model, we introduced a novel theoretical framework to consolidate research and methods developed in the field of explainable AI (XAI). This framework is supported by two fundamental definitions, namely “explanation” and “interpretation”. These definitions are further contextualized within a general pipeline that constrains other important primitives like input/output domains, and establishes a divide between low-level mathematical constructs and the high-level, human-understandable realm of (non-)functional requirements.

We show that the proposed framework is compliant with desiderata regarding explanations as defined in previous work. Moreover, existing metrics for XAI methods can be placed within the framework allowing an apples-to-apples comparison between different explanations. Finally, we show a concrete scenario where our framework can help comparing existing XAI methods, showing the extent by which each one addresses different aspects of the explainability pipeline.

5.1. Current trends and practices

We conducted an extensive review of XAI literature, allowing us to identify some current practices in the XAI community, some of which we summarize here in terms of our framework.

Most contributions focus on the development and use of explanation methods while neglecting the role of the interpretation (with notable exceptions like [31, 27]). Explanations, on the other hand, are often defined without explicit definitions of the domain and co-domain (i.e., realm of the explanans and explanandum). More recently, explainable models are trying to include richer objectives through auxiliary tasks: this strategy addresses both the underspecification of the task (conveys some of the sought after non-functional requirements) and expresses some of the invariances that are expected of the task. In domains where AI takes over or assists human-professional workers (e.g., for medical applications), interest often shifts from the prediction to the explanation such that human experts learn and gain new insights about the task.

5.2. Recommendations

Finally, we identify three aspects that future research in XAI should focus on in order to expedite the advancement of the state-of-the-art.

• Before working on the specifics of an explanation, explicitly define the non-functional requirements that a task should fulfill, and that the explanation itself will be probing for. This can be achieved by defining better hypotheses e.g., one that can be falsified [19].

• With each new explanation method a clear, measurable interpretation should be provided.

• Metrics for XAI methods should operate within the same level of abstraction w.r.t. the framework i.e., compare explanans to explanans, explanandum to explanandum, interpretation to interpretation, etc.
