In this supplementary material, we first introduce the details on network architecture (Section A) and loss functions (Section B). Then we show additional experiments and ablation study (Section C). Finally, we give the closed-form analytical solution to get the minimal alignment error of our piece-wise rigid constraint (Section D.1), analyze the least square solution of rotation (Section D.2.1), and reveal the relationship between ARAP loss and the local rigid constraint (Section D.2.2).

A. Details on Network Architecture

In this section, we describe more details of our network. It consists of three modules: an encoder-decoder network, part prediction networks, and an SDF prediction module.

Encoder-Decoder Network. The encoder-decoder network predicts correspondences on template (Figure 2 of the main paper). The encoder receives a point \( p \) from the target space \( S \), along with its predicted SDF value from the SDF prediction module as input. It then produces a vector \( l(p) \in \mathbb{R}^N \). Following that, the decoder takes \( l(p) \) as input and outputs the corresponding point \( D_{i\rightarrow tmpl}(p) \in S_{tmpl} \) in template space. Our encoder and decoder consist of 5 and 4 fully connected layers, respectively.

Part Prediction Networks. The networks \( \psi_c \) and \( \psi_d \) predict part probabilities, \textit{i.e.} \( P_h \) in Eq. 6 of the main paper, for each point. Each network divides the target shape into 20 parts, totally 40 parts together for calculating piece-wise rigid constraint, \textit{i.e.}, \( N_p = 40 \) in Eq. 6 of the main paper. Our part prediction networks \( \psi_c \) and \( \psi_d \) have 4 and 3 fully connected layers, respectively. We use SoftMax to normalize the probabilities predicted by each network. Both networks are trained in a self-supervised manner by optimizing piece-wise rigid constraint.

For each point \( p \) in a target space \( S \), \( \psi_c \) takes the output vector \( l(p) \in \mathbb{R}^8 \) of the encoder as input, and \( \psi_d \) takes the correspondence point \( D_{i\rightarrow tmpl}(p) \in S_{tmpl} \) in template space as input. Since the correspondences are consistent across shapes deformed from the same template, the part segmentation learned by \( \psi_d \) is also consistent across all shapes. The segmentation results are shown in Figure 4 in our main paper and Figure C in the supplementary material. However, the correspondences are not learned well at the beginning of training. Conceptually, the prediction of \( \psi_d \) highly depends on learned correspondences and template, so it cannot be effectively trained at the beginning of training, with highly-undertrained optimization of correspondences and template. In order to address this issue, we use \( \psi_c \) to predict part segmentation, which does not depend on correspondences on template. During training stage, we observe that \( \psi_c \) provides valid rigid constraint earlier than \( \psi_d \) and enables the network to converge faster.

SDF Prediction Module. The SDF prediction module \( \Phi \) is in charge of modeling template SDF field as well as SDF fields of other shapes in training set. With dense correspondence predicted by the encoder-decoder network, we can query SDF values from template field to reconstruct target shapes (Eq. 2 in the main paper). Inspired by Atzmon \textit{et al.} [1] that the initial scalar field contributes greatly to shape representation learning, we add the distance of an input point \( p \) to center \((0,0,0)\) to the output of the neural implicit SDF function \( \Phi \) and achieve similar initialization to Atzmon \textit{et al.} [1]. The output of SDF prediction module is formulated like [6] as \( \Phi(p|\alpha) = \phi(p|\alpha) + \|p\|_2 \), where \( \phi \) denotes a neural network for SDF prediction. The network \( \phi \) consists of 5 fully connected layers.

Other Details. Similar to the previous works [4, 9], the parameters of encoder, decoder, and SDF prediction module are all predicted by Hyper-Nets, while part probability networks have their own parameters. All the Hyper-Nets in our method consist of 5 fully connected layers with \textit{relu} as activation function. The dimension of hidden features is 256 in Hyper-Nets, and is 128 in other modules. The dimension

\*indicates corresponding author
of latent code $\alpha$ for each shape is 128.

We use the sine activation function proposed by Sitzmann et al. [8] for encoder, decoder, SDF module and part probability networks, because it has excellent property of representing complex signal and its derivative [8]. The sine activation function is in form of $f(x) = \sin(\omega x)$, and larger $\omega$ usually indicates output with higher frequency. In our experiments, $\omega$ is set to 15 in part probability networks, and set to 30 in encoder, decoder and SDF prediction networks.

### B. More Details on Loss Functions

In Section 3.4 of our main paper, we follow the idea of $L_{sdf}$ to supervise queried SDF values from template. In the following, we show the detailed formulations of the constraints. The $L_{sdf}$ is used to supervise SDF values $\Phi(p|\alpha_i)$, while the following constraints are used to supervise SDF values queried from template field $\Phi(D_{i\rightarrow tmpl}(p)|\alpha_{tmpl})$.

#### SDF Regression Constraints

The SDF regression constraints have the similar formulation to $L_{sdf}$. In order to constrain the queried SDF to have the same sign of the ground truth, we design the constraint for queried SDF value formulated as

$$L_{pbs} = \sum_{p \in S_i} |\hat{s}(p)|,$$

$$\hat{s}(p) = \begin{cases} \Phi(D_{i\rightarrow tmpl}(p)|\alpha_{tmpl}), & \text{if } \bar{s} \cdot \Phi(D_{i\rightarrow tmpl}(p)|\alpha_{tmpl}) \leq 0 \\ 0, & \text{otherwise} \end{cases}$$

(1)

where $\bar{s}$ is the ground truth SDF value. The loss weight of $L_{pbs}$ is $w_s$, which is the same as $w_s$ in the main paper (the first term of Eq. 8).

In order to supervise the normal on a represented shape, we constrain the gradient of the queried SDF field to align with ground truth normal:

$$L_{pbn} = \sum_i \sum_{p \in S_i^p} (1 - S_c(\nabla_p \Phi(D_{i\rightarrow tmpl}(p)|\alpha_{tmpl}), \bar{n})), $$

(2)

where $\bar{n}$ is the ground truth normal, and $S_c$ is cosine similarity. Note that the $L_{pbn}$ is different from $L_{pfn}$ (Eq. 9 in the main paper). The loss $L_{pbn}$ supervises normals on the represented shape, while $L_{pfn}$ supervises normals on template, which is proved to be crucial for shape representation learning by Deng et al. [4]. The weight of $L_{pbn}$ and $L_{pfn}$ is $w_n$ (which is also the weight of $\sum_{p \in S_i^p} (1 - S_c(\nabla \Phi(p|\alpha_i), \bar{n}))$ of Eq. 8 in the main paper).

We also constrain the gradient of template field to satisfy Eikonal equation: $\sum_{p \in S_{tmpl}} ||\nabla \Phi(p|\alpha_{tmpl})||_2 - 1 |$, and apply $\rho$ (the fourth term of Eq. 8 of the main paper) on template field to encourage off-surface points on template to have larger SDF values. Their weights are same as $w_{Eik}$ and $w_p$ in the main paper.

#### Reconstruction Loss

We give the detailed formulation of $L_{recon}$ in Section 3.4 of the main paper as

$$L_{recon} = \sum_{i} \sum_{p \in S_i} \|p - D_{i\rightarrow i}(p)\|^2 + \sum_{p \in S_{tmpl}} \|p - D_{tmpl\rightarrow tmpl}(p)\|^2. $$

(3)

The weight of each loss term remains the same across all subjects, specially $w_s = 3 \times 10^2$, $w_n = 50$, $w_{Eik} = 5$, $w_p = 50$, $w_{recon} = 5 \times 10^3$, $w_{reg} = 1 \times 10^5$, $w_{lr} = 10$, $w_{nbr} = 5 \times 10^4$, $w_{pr} = 3 \times 10^3$.

![Figure A: More qualitative experiments to demonstrate the ability of our method to learn template. The learned template shapes with the separate template representation are all not reasonable, and our template enables significantly better results of generated shapes than those with the separate template.](image)

**Figure A:** More qualitative experiments to demonstrate the ability of our method to learn template. The learned template shapes with the separate template representation are all not reasonable, and our template enables significantly better results of generated shapes than those with the separate template.

### C. Additional Experiments

#### C.1. Ablation Study

**Effect of Our Template Representation.** In this section, we use the same method as the main paper to further investigate the ability of our novel template shape representation architecture and show more results. Instead of representing the template shape as a latent code, we test an ablation case where a separate network only predicts template SDF like DIF. The architecture of the new template SDF module is the same as the origin SDF prediction module in our main
Table A: Ablation study on subject 50026 from D-FAUST[3] dataset. "w/o $\psi_e$" represents the model without part probabilities prediction network $\psi_e$. "w/o SDF input" represents the input of our encoder only contains coordinate $p$. It shows that $\psi_e$ can improve the performance on both Chamfer distance and geodesic distance. Using SDF as input of encoder can greatly improve the performance of our method.

**Effect of SDF input to Encoder.** In order to evaluate the effect of SDF input to encoder, we compare the Chamfer distance of shape reconstruction and geodesic distance of predicted correspondences by removing the SDF input. We also show the results using our method without input SDF on subject 50026 in D-FAUST [3] in Table A and Figure B. We observe that method without $\psi_e$ cannot converge as well as our full model, especially in the end points of the body with the large range of motion.

**C.2. More Evaluations on Model Capacity**

In this section, we show more model capacity comparisons with DIF [4] and 3D-CODED [5] using reconstructed shapes in the training set. Figure E and Figure F shows that our method outperforms both of them.

**C.3. Reconstruction from Full Observation**

In this section, we will show more qualitative experiments of our method compared with DIF [4] and 3D-CODED [5]. We generate point cloud of each subject by simulating multiple depth cameras, and then fit our shape representation model by minimizing Eq. 10 in the main paper. Figure G and Figure H show the results of humans and animals. We can observe that our method outperforms DIF and 3D-CODED, and achieves plausible shape reconstruction and correspondence results. Our method can fit shapes with large deformation effectively. Conceptually, 3D-CODED and DIF lack sufficient rigid constraints, so they cannot model subjects with large deformation properly. Although DIF can learn template SDF field, the learned shape is out of the distribution of the training data. Therefore, there are many floating components on the reconstructed shapes.

**C.4. Reconstruction from Partial Observation**

We generate point cloud of each subject by simulating a single depth camera, and then fit our representation model by minimizing Eq. 10 in the main paper. Figure I and Figure J show the qualitative experiments of shape reconstruction from partial point cloud. Our model can reconstruct shapes from partial point cloud while 3D-CODED [5] fails. Therefore, we only compare with DIF [4]. Results show that our method outperforms DIF by a large margin for partial point clouds.
C.5. Comparison with LoopReg

In this section, we compare our method with LoopReg [2] on training set. LoopReg creates a self-supervised loop to register a corpus of scans to a common 3D human model (i.e., SMPL [7]), which can model correspondences between human pairs. As shown in Table B, our method outperforms LoopReg on both IoU and corr.

</tbody>
</table>

Table B: Capacity evaluation on D-FAUST with LoopReg [2]

C.6. Qualitative Experiment on Part Segmentation

In this section, we compare our method with the stitched puppet [13]. The stitched puppet [13] is a shape representation method that manually segments the represented shape into multiple parts and combines the parts into human body shapes with different poses. As shown in Figure C, our self-supervised method achieves comparable results.

C.7. Failure Cases

We show several failure cases in Figure D where floating components make Chamfer distance increase. Although these shapes have fine human surface geometry, they have large Chamfer distance because of the floating components far from the body.

D. Details on Rigid Constraint

In this section, we will give details on the closed-form solution of piece-wise rigid constraint in Section 3.3 of the main paper. Then, we will give theoretic analysis on our local rigid constraint, in which we elaborate on the relationship between the proposed constraint with implicit representation in Section 3.2 of the main paper and the traditional As-Rigid-As-Possible loss [11] that was originally proposed for discrete mesh deformation.

D.1. Closed-Form Solution of Piece-wise Rigid Constraint

We follow Sorkine-Hornung et al. [11] to give a closed-form solution of the minimal rigid transformation error of our piece-wise rigid constraint $L_{pr}$ (Eq. 6 of our main paper). Detailed proof can be found in [11]. In this section, we use the same notions as [11] for easy understanding.

Denote $\mathcal{P} = \{p_1, p_2, \ldots, p_n\}$ and $\mathcal{Q} = \{q_1, q_2, \ldots, q_n\}$ to be corresponding points in $\mathbb{R}^d$. Therefore, the optimal rigid transformation $(R, t)$ between $\mathcal{P}$ and $\mathcal{Q}$ can be estimated by minimizing the following alignment error as

$$F = \sum_{i=1}^{n} w_i \|R_{x_i} + t - q_i\|^2,$$

where $R \in SO(d)$ is rotation matrix and $t \in \mathbb{R}^d$ is translation.

First, Sorkine-Hornung et al. [11] proved that the optimal translation $t$ can be expressed as

$$t = \bar{q} - Rp,$$

where $\bar{q}$ and $\bar{p}$ are the centroid of $\mathcal{Q}$ and $\mathcal{P}$

$$\bar{p} = \frac{\sum_{i=1}^{n} w_i p_i}{\sum_{i=1}^{n} w_i}, \quad \bar{q} = \frac{\sum_{i=1}^{n} w_i q_i}{\sum_{i=1}^{n} w_i}.$$

Incorporate the optimal $t$ into Eq. 4, and then we get the loss function $F$ as

$$F = \sum_{i=1}^{n} w_i \|R_{x_i} - \bar{p} - (q_i - \bar{q})\|^2.$$  

(7)

Giving the definitions as follows

$$x_i := p_i - \bar{p}, \quad y_i := q_i - \bar{q},$$  

we can set the translation $t$ to be zero, and then focus on the estimation of $R$ by optimizing the following equivalent loss function

$$L = \min_{R} \sum_{i=1}^{n} w_i \|Rx_i - y_i\|^2.$$  

(9)
Denote $W = \text{diag}(w_1, ..., w_n), X = [x_1, x_2, ..., x_n], Y = [y_1, y_2, ..., y_n]$. Then the loss function $L$ can be effectively calculated with the following closed-form solution

$$
L = \sum_{i=1}^{n} w_i (\|x_i\|^2 + \|y_i\|^2) - 2S_{\sigma}(XWY^T)
$$

$$
S_{\sigma} = \begin{cases}
\sigma_1 + \sigma_2 + ... + \sigma_{d-1} + \sigma_d, & \text{if } \det(UV^T) = 1 \\
\sigma_1 + \sigma_2 + ... + \sigma_{d-1} - \sigma_d, & \text{if } \det(UV^T) = -1,
\end{cases}
$$

(10)

where $U, V$ are the left and the right singular matrices of $XWY^T$, and $\{\sigma_i\}$ are singular value of $XWY^T$ in descending order. Moreover, the gradient of $S_{\sigma}$ is a rotation matrix, which does not contain large value and enables stable learning process.

In order to calculate the 3D alignment error $L$, we only need several efficient operations, such as solving SVD of $3 \times 3$ square matrix $XWY^T$ and conducting point-wise additions and multiplications.

In our problem, $P$ and $Q$ are consisting of the points in the target space $\{p\}$ and the correspondence $\{D_{i\rightarrow\text{tmpl}}(p)\}$ in the template space, respectively. Therefore, the piecewise rigid loss $L_{pr}$ (Eq. 6 of our main paper) can be expressed in closed-form as

$$
\min_{R_h,p} \sum_{p \in S_h^p} P_h(p)\|\left(R_h p + t_h - D_{i\rightarrow\text{tmpl}}(p)\right)\|^2
$$

$$
= \sum_{p \in S_h^p} P_h(p)(\|x\|^2 + \|x_{i\rightarrow\text{tmpl}}\|^2) - 2S_{\sigma}(XW_hX_{i\rightarrow\text{tmpl}}^T)
$$

(11)

where $x$ and $x_{i\rightarrow\text{tmpl}}$ are the points in the target space and their correspondence in template after removing their respective centroid as

$$
x = \bar{p}
$$

$$
x_{i\rightarrow\text{tmpl}} = D_{i\rightarrow\text{tmpl}}(p) - \bar{D}_{i\rightarrow\text{tmpl}}(p),
$$

(12)

and $\bar{p}$ and $\bar{D}_{i\rightarrow\text{tmpl}}(p)$ are their respective centroid as Eq. 6. The $j$-th column of $X \in \mathbb{R}^{3 \times n}$ is $x$ derived from the $j$-th point $p$, each column of $X_{i\rightarrow\text{tmpl}} \in \mathbb{R}^{3 \times n}$ is the correspondence $x_{i\rightarrow\text{tmpl}}$ of the $j$-th point $p$. $P_h(p)$ is the probability that point $p$ belongs to $h$-th part, and $W_h$ is a $n \times n$ diagonal matrix, its $j$-th diagonal element is the predicted part probability $P_h$ of the $j$-th point $p$.

D.2. Analysis on Local Rigid Constraint

D.2.1 Analysis on Least Square Solution of Rotation

In this section, we give further analysis on the formulation of closest rotation matrix of $J(D_{i\rightarrow\text{tmpl}})$. With singular value decomposition (SVD), we get $J(D_{i\rightarrow\text{tmpl}}) = U\Sigma V^T$. Given the properties of the determinant, we know that $\det(J(D_{i\rightarrow\text{tmpl}})) = \det(U)\det(\Sigma)\det(V^T)$. According to the definition of the singular value, the singular values of $J(D_{i\rightarrow\text{tmpl}})$ (i.e. diagonal items of $\Sigma$) are always positive. Therefore, $\det(J(D_{i\rightarrow\text{tmpl}}))$ has the same sign as $\det(U)\det(V^T)$, i.e. $\det(UV^T)$. When $\det(J(D_{i\rightarrow\text{tmpl}})) < 0$, its closest orthogonal matrix $UV^T$ has negative determinant. However, a rotation matrix must have positive determinant. To this end, previous method [12] figured out the closet rotation that has positive determinant. $R = USV^T$ (R have positive determinant) of $J(D_{i\rightarrow\text{tmpl}})$ with a diagonal matrix $S = \text{diag}(1, 1, \det(UV^T))$.

D.2.2 Equivalence between Local Rigid Constraint and ARAP

In this section, we will prove that our implicit local rigid constraint is equivalent to traditional As-Rigid-As-Possible (ARAP) loss in infinite small scope. ARAP loss [10] is generally defined on discrete representations such as mesh, while we find that with the closed form of alignment error Eq. 10 ARAP loss can be extended to continuous implicit representation for infinite small scope.

According to Sorkine et al. [10], ARAP loss on mesh is defined as

$$
E = \min_{R} \sum_{j \in N(i)} w_{ij} \| (p'_i - p'_j) - R_i(p_i - p_j) \|^2.
$$

(13)

In our method, we represent the shape as implicit field instead of mesh in original ARAP [10], so there is not explicit adjacency relation for our shape representation. It is barely addressed and highly challenging to constrain ARAP in the continuous implicit shape representation.

For a sampling point $p$, we assume the adjacent points of $p$ are uniformly distributed on the surface of a sphere centered at $p$, which can be formulated as $p + \omega s$, where $\omega$ is an arbitrary unit vector. For simplicity, we consider $w_{ij}$ as 1.

Considering the adjacent points within the infinitely-small volume, we denote adjacent points as $p + \omega ds$.

(14)

where $ds$ is infinitely small length.

Denote the mapping from $p$ to $p'$ as $D(p)$ and $\frac{\partial D(p)}{(p')^T}$, i.e. $\frac{\partial D(p)}{\partial (p')^T}$, i.e. $J(D_{i\rightarrow\text{tmpl}})(p)$, as $J$. In our case, $p$ is in the target shape space and $p'$ is in the template shape space. Then we have the following equation by Taylor expansion

$$
D(p + \omega ds) = D(p) + J\omega ds + o(ds).
$$

(15)

According to Eq. 10, we can also get a closed-form solution for ARAP loss in Eq. 13. Because $\omega$ is evenly distributed on the sphere, $\sum \omega = 0$, the centroid of $p + \omega ds$
is \( \mathbf{p} \) and the centroid of \( D(\mathbf{p}) + J_\omega ds \) is \( D(\mathbf{p}) \). After incorporating \( \mathbf{p} + \omega ds \) and \( D(\mathbf{p}) + J_\omega ds \) and their centroids into Eq. 8, we get \( x_i = \omega ds \) and \( y_i = J_\omega ds + \sigma(ds) \), and incorporate \( x_i \) and \( y_i \) into Eq. 10, then we can get the following equation by ignoring the infinitesimal of higher order

\[
E = \sum_\omega \| \omega ds \|^2 + \| J_\omega ds \|^2 - 2S_\sigma \sum_\omega \omega^T J^T ds^2
\]

\[
= ds^2 \sum_\omega (\| \omega \|^2 + \| J_\omega \|^2) - 2ds^2 S_\sigma \left( \sum_\omega \omega^T J^T \right).
\]

Since \( \omega \) is uniformly distributed, we use integration instead of summation.

\[
E = ds^2 \left( \int_{S^2} \| \omega \|^2 d\omega + \int_{S^2} \| J_\omega \|^2 d\omega \right) - 2S_\sigma \left( \int_{S^2} \omega^T J^T d\omega \right),
\]

where \( S^2 \) represents the surface of a unit sphere embedded in the 3-dimensional space, and each term will be analyzed in the following part.

Since \( \| \omega \|^2 = 1 \), the first term can be easily calculated as the area of the sphere, i.e. \( 4\pi \).

Then the second term can be simplified as

\[
\int_{S^2} \| J_\omega \|^2 d\omega = \int_{S^2} \omega^T J^T J_\omega d\omega
\]

\[
= \int_{S^2} \sigma \left( \omega^T J^T J \right) d\omega
\]

\[
= \sigma \left( \int_{S^2} J^T J \omega^T d\omega \right) = \sigma \left( J^T J \int_{S^2} \omega^T d\omega \right).
\]

To solve the above function, we need to know the result of \( \int_{S^2} \omega^T d\omega \). We use spherical coordinates to calculate the integration.

\[
\omega = \left( \sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta \right)^T = \left( \sin \theta \cos \phi, \sin \theta \sin \phi, 0 \right)^T + (0, 0, \cos \theta)^T
\]

\[
\int_{S^2} \omega^T d\omega = \int_0^\pi \int_0^{2\pi} \sin \theta \left( \begin{array}{c} 0 \\ 0 \\ \cos \theta \end{array} \right) + \left( \begin{array}{c} \sin \theta \cos \phi \\ \sin \theta \sin \phi \\ 0 \end{array} \right) \right) d\phi d\theta
\]

\[
= \int_0^\pi \int_0^{2\pi} \sin \theta \left( \begin{array}{c} 0 \\ 0 \\ \cos \theta \end{array} \right) + \left( \begin{array}{c} \sin \theta \cos \phi \\ \sin \theta \sin \phi \\ 0 \end{array} \right) \right)^T d\phi d\theta
\]

\[
\int_0^\pi \int_0^{2\pi} \sin \theta \left( \begin{array}{c} 0 \\ 0 \\ \cos \theta \end{array} \right) + \left( \begin{array}{c} \sin \theta \cos \phi \\ \sin \theta \sin \phi \\ 0 \end{array} \right) \right)^T d\phi d\theta = \int_0^\pi \int_0^{2\pi} \sin \theta \left( \begin{array}{c} \sin \theta \cos \phi \\ \sin \theta \sin \phi \\ 0 \end{array} \right) \right)^T d\phi d\theta
\]

Consider the periodicity of \( \int_0^{2\pi} \sin 2\phi d\phi = 0 \) and \( \int_0^{2\pi} \cos 2\phi d\phi = 0 \):

\[
= \int_0^\pi \int_0^{2\pi} \sin \theta \left( \begin{array}{c} \sin \theta \cos \phi \\ \sin \theta \sin \phi \\ 0 \end{array} \right) \right)^T d\phi d\theta
\]

Consider the periodicity of \( \int_0^{2\pi} \sin 2\phi d\phi = 0 \):

\[
= \int_0^\pi \int_0^{2\pi} \sin \left( \begin{array}{c} \sin^2 \theta \cos^2 \phi \\ \sin^2 \theta \sin^2 \phi \\ 0 \end{array} \right) \right) d\phi d\theta
\]

Denote singular value decomposition (SVD) of \( J \) to be \( J = U \Sigma V^T \). Then Eq. 18 can be calculated as

\[
tr(J^T J) \int_{S^2} \omega^T d\omega = tr(J^T J \frac{4\pi}{3})
\]

\[
= \frac{4\pi}{3} tr(J^T J) = \frac{4\pi}{3} tr(V \Sigma U^T U \Sigma V^T)
\]

\[
= \frac{4\pi}{3} tr(V \Sigma \Sigma V^T) = \frac{4\pi}{3} tr(V^T \Sigma \Sigma)
\]

\[
= \frac{4\pi}{3} tr(\Sigma) = \frac{4\pi}{3} (\sigma_1^2 + \sigma_2^2 + \sigma_3^2),
\]

where \( \sigma_1, \sigma_2, \sigma_3 \) are singular values in descending order.

With the above result of \( \int_{S^2} \omega^T d\omega \), the third term of Eq. 17 can be calculated as

\[
S_\sigma \left( \int_{S^2} \omega^T J^T d\omega \right)
\]

\[
= S_\sigma \left( \int_{S^2} (\omega^T J)^T d\omega \right)
\]

\[
= S_\sigma \left( \int_{S^2} \omega^T d\omega \right) = S_\sigma \left( \frac{4\pi}{3} J \right)
\]

\[
= \frac{4\pi}{3} (\sigma_1 + \sigma_2 + det(U V^T) \sigma_3).
\]

We can simplify Eq. 17 with the above results of its three items as

\[
E = \frac{4\pi}{3} ds^2 \left( 3 + \sigma_1^2 + \sigma_2^2 + \sigma_3^2 - 2(\sigma_1 + \sigma_2 + det(U V^T) \sigma_3) \right)
\]

\[
= \frac{4\pi}{3} ds^2 ((\sigma_1 - 1)^2 + (\sigma_2 - 1)^2) + (\sigma_3 - det(U V^T))^2.
\]
Our $L_{\text{arap}}$ in Section 3.2 of our main paper has the following formulation

$$L_{\text{arap}} = \text{smooth}L_1(\sigma_1, 1) + \text{smooth}L_1(\sigma_2, 1) + \text{smooth}L_1(\sigma_3, \det(UV^T))$$

(25)

If $\sigma_1$, $\sigma_2$ and $\sigma_3$ are close to 1 and $UV^T = 1$, the smooth$L_1$ loss becomes $L_2$ loss. By ignoring the scale term, $L_{\text{arap}}$ has the same form as Eq. 24.

Therefore, our implicit local rigid constraint is equivalent to traditional As-Rigid-As-Possible (ARAP) loss in infinite small scope.
