Enhancing CLIP with GPT-4: Harnessing Visual Descriptions as Prompts

Mayug Maniparambil, Chris Vorster, Derek Molloy, Noel Murphy, Kevin McGuinness, Noel E. O’Connor  
ML Labs, Dublin City University, Dublin, Ireland

Abstract

Contrastive pretrained large Vision-Language Models (VLMs) like CLIP have revolutionized visual representation learning by providing good performance on downstream datasets. VLMs are 0-shot adapted to a downstream dataset by designing prompts that are relevant to the dataset. Such prompt engineering makes use of domain expertise and a validation dataset. Meanwhile, recent developments in generative pretrained models like GPT-4 mean they can be used as advanced internet search tools. They can also be manipulated to provide visual information in any structure. In this work, we show that GPT-4 can be used to generate text that is visually descriptive and how this can be used to adapt CLIP to downstream tasks. We show considerable improvements in 0-shot transfer accuracy on specialized fine-grained datasets like EuroSAT (∼ 7%), DTD (∼ 7%), SUN397 (∼ 4.6%), and CUB (∼ 3.3%) when compared to CLIP’s default prompt. We also design a simple few-shot adapter that learns to choose the best possible sentences to construct generalizable classifiers that outperform the recently proposed CoCoOP by ∼ 2% on average and by over 4% on 4 specialized fine-grained datasets. The code, prompts, and auxiliary text dataset is available at github.com/mayug/VDT-Adapter.

1. Introduction

Contrastive pre-training of large-scale VLMs has demonstrated remarkable image classification performance on open-set classes. Models like CLIP [25] and ALIGN [12] are pretrained on web-scale datasets consisting of image-text pairs (over 400 million and 1.8 billion respectively), resulting in a highly generalizable model with competent 0-shot domain adaptation capabilities. While vanilla supervised training is performed on a closed set of concepts or classes, CLIP pretraining uses natural language. This results in a joint text-vision embedding space that is not constrained to a fixed set of classes. In CLIP, the classifier is constructed by plugging the class name into a predetermined prompt template like ‘a photo of {class name}'. A straightforward way to adapt CLIP to different domains is by prompt engineering, which usually involves modifying the prompt template to include semantic information about the target task. For example, to classify bird images, one could construct a prompt ‘a photo of {classname}, a type of bird'. This prompt engineering process, however, is not optimal because it: 1.) requires domain expertise in the target domain; 2.) has high variance – small changes to the prompt result in large variation in performance; 3.) has a fixed prompt template for all the classes, therefore only the class name in the prompt provides the classification anchor, which might not contain enough information to distinguish different classes. For example, in Fig 1 we see an image of a Green Heron, which from the name would suggest that it is predominantly a green-colored bird and we would assume that it is similar to Green Woodpecker if we have never seen either bird. However, we can see that it is in fact a blackish-brown bird with a chestnut-colored neck and visually more similar to a bird like the Black Bittern. For 0-shot transfer to fine-grained datasets like this to work well, CLIP has to either have seen and associated images of a Green Heron to the text ‘Green Heron’ from its large pretraining dataset or additional information in the form of visually descriptive textual (VDT) information is required. Here we define VDT as a set of sentences that describe the visual features of the class under consideration including shape, size, color, environment, patterns, composition, etc. While most humans can identify many different common bird species just from their names, they would need access to an ornithology taxonomy of bird descriptions to identify more rare bird species. Similarly, we argue that CLIP’s 0-shot accuracy can be improved by incorporating VDT information into the prompts. As shown, in Fig 1, including VDT information like black crown and black rump moves the classification prototype of Green Heron away from the classification prototype of Green Woodpecker and towards that of Black Bittern in the text-encoder’s embedding space.

\(^1\)Corresponding author: mayugmaniparambil@gmail.com
In this work, we first show that we can use VDT information for each class in the target domain to construct class conditional prompts that achieve performance improvements over CLIP’s default prompt. We show this on the CUB dataset [29] by constructing sentences from domain experts about the bird species in Section 3.2.1 as they are readily available as part of the dataset.

However, we acknowledge that domain expert annotations are costly and time-consuming to obtain, hampering the scalability of our method to other datasets. To address this, we focus on the recent advances in generative pre-trained Large Language Models (LLMs) like GPT-4 to construct these class conditional prompts in a manner easily scalable to other datasets. These models are a good fit for the task of constructing sophisticated prompts, because: 1) they are a condensed form of human knowledge (trained on web-scale text data) [33]; 2) they can be manipulated to produce information in any form or structure which makes compatibility with CLIP’s prompt style relatively simple. Therefore we use GPT-4 to construct visually descriptive textual information about the classes with special emphasis in the GPT-4 prompts about visual cues like shape, color, structure, and compositionality. We use the generated VDT information to construct prompt ensembles that are passed through CLIP’s text encoder and aggregated to generate classifiers that are then used for 0-shot classification. Using GPT-4 circumvents the need for domain knowledge and conveniently provides class conditional prompts. Prompt ensembling the VDT sentences reduce CLIP’s performance sensitivity to small changes in the prompt. We show performance improvements over vanilla CLIP with the default prompt on 12 datasets with an average improvement of 2% and even better improvements in fine-grained datasets like EuroSAT (∼ 7%), DTD (∼ 7%), SUN397 (∼ 4.6%), and CUB (∼ 3.3%). The prompts and all the auxiliary class information are released publicly along with the code.

Finally, we design a simple adapter that learns to adaptively select and aggregate the best sentences for any given dataset and show that making use of this additional VDT information improves the few-shot domain transfer performance of CLIP as well. We demonstrate the few-shot adaptation performance for the recently proposed Base-to-New setting on a benchmark of 12 datasets and outperform recent methods like CoOp [36] and CoCoOp [35] despite having fewer model parameters, shorter training time, and a simpler model architecture.

In short, our contributions are as follows:

1. We show that including visually descriptive textual (VDT) information in prompts results in better 0-shot domain transfer performance of CLIP.
2. We use GPT-4 to generate VDT sentences in a scalable manner and show consistent performance improvements over CLIP in 0-shot domain transfer.
3. We design a simple adapter network to make use of this extra information for few-shot transfer and show performance improvements over methods like CLIP-Adapter and CoCoOp [35] for few-shot domain transfer in the Base-to-New setting.
4. We release all the VDT information for all 12 datasets to promote further research in multi-modal prompt and adapter design for low-shot domain transfer of large VLMs.

2. Related Works

2.1. Vision Language Models

Recent VLMs [12, 25, 8] jointly learn the vision and language encoders and have demonstrated impressive 0-shot domain transfer performance. As mentioned in [36], this can be attributed to transformer networks [28], contrastive losses [3, 10], and web-scale training datasets [25, 13]. While our GPT-generated prompt ensembles are similar to CLIP’s prompt ensembles, CLIP’s prompt ensembles were constructed and tuned manually, and are class agnostic, while ours were generated by GPT models that were prompted to provide VDT information for each class.

2.2. Prompt Learning

CoOp [36] successfully used prompt learning in VLMs but had generalizability limitations due to overfitting on the few-shot dataset [35]. In response, CoCoOp was proposed, enhancing performance with image-conditioned prompt learning using a meta-network, albeit at a higher resource cost. We address generalizability differently by using class conditional VDT information. Our simpler and more efficient model, CLIP-A-self, outperforms CoCoOp in the Base-to-New few-shot setting.

2.3. Few-shot adapters for Vision Language models

CLIP-Adapter [9] (CLIP-A) offers a simpler few-shot transfer method for VLMs, utilizing an MLP trained on fixed image/text encoders. Our CLIP-A-self is different from CLIP-A in that we apply a self-attention mechanism on the set of all sentences for any class, learning to select and aggregate the best subset of VDT information for the dataset from the few-shot training set. Although Tipadapter [34] showed superior performance on base classes with a cache model, it’s inapplicable in the Base-to-New setting due to its reliance on few-shot test class examples, making it irrelevant for our comparison.

2.4. Semantic information from Large Language Models

Recent advancements in transformer-based language models, particularly the GPT family [2, 22], have demonstrated exceptional abilities in semantic extraction from intricate texts. Their application to vision tasks has emerged as an active area of research. [20] employs Palm540B LLM [4] to generate semantic data for unsupervised class embedding vectors in 0-shot classification, but only tests on three legacy datasets. Our research presents results on a modern benchmark of 12 datasets. Recently, [24, 19] leverage GPT-3 for class conditional prompts to enhance CLIP’s 0-shot domain transfer on 6 datasets. While [19] focuses on using GPT-3 to construct visual descriptors that aid in the interpretability of CLIP’s predictions during 0-shot domain transfer, we argue that 0-shot domain transfer performance improves with the inclusion of high-quality VDT information. Hence, we make use of GPT-4 for richer, more diverse, and more accurate VDT information. Concurrent work [16] leverages GPT-3 to generate image-specific fine-grained text by matching GPT-generated text candidates in CLIP’s embedding space and uses them for improving the downstream classification.

While [19] utilize GPT-3, probability ensemble, and highlight VDT’s role in 0-shot transfer, our method differs. We use GPT-4 for auxiliary data collection, perform ensemble in word-encoder space, and introduce a few-shot adapter for optimal VDT selection in few-shot transfer. [27] uses GPT-3 for prompt construction in diffusion models to generate images for support sets while our work only uses GPT4 to acquire auxiliary text data. To our knowledge, we are the first to prompt GPT-4 for visually descriptive sentences to improve CLIP’s 0-shot and few-shot transfer.

3. Methodology

3.1. Review of CLIP and CLIP-Adapter

Through contrastive pretraining on large image-text datasets, CLIP performs classification on various concepts, aligning related images and texts in a shared embedding space, while separating dissimilar ones. After pretraining, CLIP directly performs image classification on the target dataset without any finetuning. First, we review how the CLIP model performs 0-shot classification on an open set.

The CLIP model, comprising a vision and language model, encodes an image and its corresponding caption into visual and textual embeddings, respectively. During inference, these embeddings are compared using cosine similarity. Given an image \( I \in \mathbb{R}^{H \times W \times C} \), where \( H \), \( W \), \( C \) denotes the height, width, and number of channels of the image, the vision encoder transforms the image into the joint embedding space to get the image features \( f \in \mathbb{R}^D \) where \( D \) represents the dimension of the features.

During inference, a prompt template such as ‘A photo of {classname}’ is used to generate sentences for \( K \) different classes and passed through the text-encoder to yield classifier weight matrix \( W \in \mathbb{R}^{D \times K} \). Prediction probabilities are then calculated by multiplying image feature \( f \) with \( W \) and applying a softmax function:

\[
f = \text{Backbone}(I), \quad p_i = \frac{\exp(W_i^T f)/\tau}{\sum_{j=1}^{K} \exp(W_j^T f)/\tau}, \quad (1)
\]
In CLIP [25], 0-shot domain transfer utilizes domain-specific information in the prompt template, such as ‘A photo of a {class-name}, a type of bird’ for bird images. [25] reports that careful prompt design and prompt ensembling are important to improve 0-shot classification accuracy. Prompt ensembling is achieved by constructing several prompts for each class and then averaging the classification vectors. In our work, we show that prompt ensembles of VDT improve CLIP’s 0-shot domain transfer.

CLIP-A [9] is a learnable MLP adapter applied to image and/or word encoder features for few-shot transfer to target datasets. During few-shot transfer, given N images per class with labels, denoted as \((x_{i,k}, y_{i,k})_{i=1, k=1}^{N,j=K}\), K classifier weights are constructed using the prompt template \(H\) and text encoder \(g\) as \(W = g(H(classname\{\{y_{i,k}\}\}))\). The image features \(f\) and text features \(W\) pass through the learnable adapters \(A_e, A_t\) to get adapted features as follows.

\[
    f^* = \alpha A_e(f)^T + (1 - \alpha)f, \tag{2}
\]

\[
    W^* = \beta A_t(W)^T + (1 - \beta)W. \tag{3}
\]

The hyperparameters \(\alpha\) and \(\beta\) blend CLIP’s knowledge with fine-tuned knowledge to avoid CLIP-Adapter overfitting. Logits are calculated as per Eqn 1, and cross entropy loss over the entire training set \((x_{i,k}, y_{i,k})_{i=1, k=1}^{N,j=K}\) is used to optimize \(A_e, A_t\).

In the All setting, few-shot transfer is tested on a hold-out dataset with images from the \(K\) classes used in training. In the Base-to-New setting, proposed by [35], the evaluation occurs on \(U\) non-overlapping classes. Our model is evaluated in the more practical Base-to-New setting.

### 3.2. Language Model Prompt Design

In this section, we demonstrate how VDT enhances CLIP’s 0-shot transfer capabilities and outline our method for generating class-specific prompts with an LLM.

#### 3.2.1 Visual Descriptive Sentences

[25] demonstrates that careful prompt design and prompt ensembling improve the 0-shot classification performance of CLIP. Here we ask the question: What type of information can be appended to the prompt template to improve the 0-shot domain transfer performance? We show that appending visually descriptive information to the prompt template and ensembling improves the 0-shot performance over the default prompt and prompts containing non-visual information.

Using the CUB dataset with expert annotations, we contrast the 0-shot performance of visual and non-visual prompt ensembles. For the visual prompts, we take class attribute vectors detailing attributes like color, pattern, shape, etc., for 28 bird body parts, leading to 312 scores per bird.

<table>

<td>53.0</td>
<td>57.7</td>
<td>57.4</td>
</tr>
</tbody>
</table>

Table 1: Comparing visual and non-visual prompt ensembles for 0-shot domain transfer to the CUB dataset.

We use the most pronounced attribute-value pairs to form 28 visual prompts (denoted Visual-GT) such as ‘A photo of Green Heron’. Green Heron has a greenish-black head cap. Conversely, for non-visual prompts (denoted Non-Visual-GT), we collect information on bird calls, migration, behavior, and habitat, yielding 12 different prompts like ‘A photo of Green Heron. The green heron’s bird call is a loud, harsh “skewow” per class.

We derive classification vectors for Visual-GT and Non-Visual-GT by averaging class-level sentence embeddings within CLIP’s joint embedding space, considering its 77-token limit. Table 1 shows no improvement using Non-Visual-GT prompts over the default, yet a 4% improvement with Visual-GT.

#### 3.2.2 Prompting LLMs for visually descriptive information

In the prior section, we highlighted the use of expert VDT information in creating class-specific prompts to enhance CLIP’s 0-shot performance. However, acquiring expert annotations is both expensive and time-consuming. To overcome this, we utilize GPT language models, known for their large-scale knowledge and flexibility [33]. Our approach involves using GPT-4 to generate visual descriptions for any given dataset thereby aiding in the construction of prompt ensembles for CLIP in a scalable manner.

Our prompting strategy takes inspiration from chain-of-thought prompting [30] and is as follows: First, we ask GPT-4 to list all the attributes that may be necessary to discriminate between images of the \(K\) classes under consideration. Second, we ask GPT-4 to provide the values for all these attributes for all the \(K\) classes as sentences. Example for the CUB dataset is shown on the left side of Fig 1.

The last row in Table 1 shows that the GPT-4 generated
Figure 2: CLIP-A-self, our simple self-attention based adapter learns to select and aggregate the most relevant subset of Visually Descriptive Text (VDT) to generate more generalizable classifiers. First, we prompt GPT-4 to generate VDT, N sentences for K classes that are then passed through the text encoder to get embeddings for each of the N*K sentences. Self-attention is applied over the N sentences of each class and averaged to get K adapted classifier embeddings.

Table 3: Results of 0-shot transfer on 12 datasets with ViT-B/16.

visual sentences’ performance is similar to that of sentences generated from the class attribute vectors annotated by domain experts. We follow the same simple strategy for all the datasets in the benchmark suite to generate visually descriptive sentences in a scalable and flexible manner and use them to construct prompt ensembles.

3.3. Simple few-shot adapters for visual sentences

We design a simple adapter that can use VDT information to improve the few-shot transfer of CLIP to the target datasets. Similar to the CLIP-A text, we append a small set of learnable parameters to the output of the word encoder and train the adapter using cross-entropy loss. Our CLIP-A-self uses a self-attention layer that applies attention over the embeddings of the different sentences for each class and averages the output to get the final classification vector.

Table 4: Comparing our CLIP-A-self against other methods on average accuracy over 12 datasets.

<table>
<thead>
<tr>

<td>77.78</td>
</tr>
</tbody>
</table>
For the self-attention adapter, we apply vanilla self-attention [28] over all the visual descriptive sentences such that during training it learns to select and aggregate the most relevant visual sentences for identifying each class. Just like before, we first obtain the classification vector for all sentences \( W_s \in \mathbb{R}^{K \times M \times D} \) and pass them as the key, query, and value to the self-attention module \( B_{self} \) and average out the output tokens to get the final classification vector \( W^* \). Here the attention is applied over the \( M \) different visually descriptive sentences.

\[
W_{avg} = \frac{1}{M} \sum_{m=1}^{M} W_{a}^m
\]  

\[
\{ W_{a,m,k} \}_{1}^{M} = B_{self}(\{ W_{a,m,k} \}_{1}^{M}, \{ W_{m,k} \}_{1}^{M}, \{ W_{m,k} \}_{1}^{M})
\]  

\[
W_{a-mean} = \frac{1}{M} \sum_{m=1}^{M} W_{a,m,k}
\]

\[
W^* = \beta W_{a-mean}^T + (1 - \beta) W_{avg}
\]

We finally obtain the new adapter classifier weights \( W^* \in \mathbb{R}^{D \times K} \) that have been adapted to focus on the most visually discriminative information among the \( M \) visually descriptive sentences for any given dataset. We make use of \( I \) to calculate the probabilities and predict the image category by selecting the class with the highest probability.

During the few-shot training only the weights of the adapter network \( B_{self} \) are trained using cross-entropy loss.

### 4. Experiments

We assess the significance of visual sentence ensembles in two scenarios: (i) we gauge visual sentence quality by comparing an ensemble of these prompts with CLIP’s default prompts across 12 benchmark datasets; (ii) we contrast the performance of adapters using these visual prompts against other few-shot transfer techniques in Base-to-New class generalization within a dataset. Prior to discussing the results, we detail the datasets and experimental setup.

#### 4.1. Datasets

For 0-shot transfer with visual sentences, we test on All classes across these datasets while for the Base-to-New setting, following [35], we equally sample classes for base and new sets without overlap. We use the 150-base and 50-new class split from ZSL and few-shot literature [31, 18] for CUB. Like [35], our CLIP-A-self is evaluated on the 16-shot setting for easier comparison with other methods.

#### 4.2. Baselines

We compare the performance of visual sentences ensemble on 0-shot transfer against the CLIP model [25] whose default prompts for each dataset have been extensively fine-tuned using a test set. We also compare against DCLIP [19] a recent work that uses GPT-3 to generate VDT information for 0-shot transfer. We compare our CLIP-A-self against two prompt learning methods CoOp [36] which learns static prompts and CoCoOp [35] which learns a dynamic prompt that is specifically designed to improve Base-to-New transfer. We also compare our CLIP-A-self against CLIP-A [9] due to the similarity in architecture and to show that the performance improvements are from making use of the visual sentences and not from the just adapting the text features.

#### 4.3. Training settings

Our implementation is based on CoOp’s and CLIP-A’s code. We make all our comparisons on VIT CLIP backbone i.e., VIT-B/16. We take the results for CoOp and CoCoOp for all datasets (except CUB) from their respective papers, while we make use of practices from the respective papers like context length set to 4 and context initialization to “a photo of” to ensure the best results on the CUB dataset. For CLIP-A, we re-run all experiments on VIT-B/16 backbone as they were not reported in the paper. For all adapter models including ours, we only tune the residual ratio \( \beta \) hyperparameter. For CLIP-A, we use the version where the MLP is applied on top of the visual encoder as it performed the best [9]. We make use of May version of GPT-4 for obtaining the auxiliary dataset.

#### 4.4. GPT generated visual sentences improve 0-shot transfer.

We compare the performance of CLIP-GPT prompt ensemble with the default prompts of CLIP in Table 3. GPT-generated prompt ensemble improves upon the performance of CLIP 0-shot by \( 2\% \) on average over 12 datasets. The improvement over CLIP-ZS is significant; over \( 5\% \) for specialized fine-grained datasets like CUB, SUN397, EuroSAT, and DTD and over \( 2\% \) for Oxford-flowers and Oxford-pets. This shows that CLIP does not recognize several of the classnames in these datasets and describing the class in the form of visually descriptive sentences results in better classifiers from the text-encoder and better classification accuracy. It is also worth noting that only including the visually descriptive sentences in the prompts can help improve the performance of general datasets like ImageNet (over \( 4\% \))
Table 5: Comparison of CLIP-A-self with CLIP, CoOp and CoCoOp in the Base-to-New generalization setting. For prompt learning-based methods (CoOp and CoCoOp), their prompts are learned from the base classes (16 shots). The results strongly justify the importance of including extra VDT information. H denotes Harmonic mean (to highlight the generalization trade-off [31]).

and Caltech-101 (over 1%) too. For all other datasets, the transfer performance matches that of CLIP, with the exception being the action recognition dataset UCF-101. We inspected the sentences generated for UCF-101 and notice that several of the sentences generated by GPT involves temporal information instead of visual descriptions and we believe this could be the reason for the drop in accuracy. However, we notice in Section 4.5.1 that the self-attention module of the few-shot adapter learns to emphasize the visual sentences out of the generated sentences which might explain the improvement in the performance of few-shot adapters in the new setting in Section 4.5. We also compare against recent work [19] on their subset of 6 datasets for VIT-B/16 encoder in 2. We see that using the larger GPT-4 model over the GPT-3 model results in much higher improvements for specialized datasets like DTD (∼5%) and EuroSAT (∼6%). We compare the text used by [19] against our GPT4-generated VDT in the supplementary.

4.5. GPT-Adapters improve few-shot transfer performance.

We compare the performance of our CLIP-A-self against CLIP, CoOp, and CoCoOp on the benchmark suite of 12 datasets in the Base-to-New setting in Table 5. Here we see that GPT-Adapters that make use of the VDT information outperform CoCoOp by 3% in the new setting while
maintaining similar performance to that of CoOp in the base setting on the average accuracy over 12 datasets. This is impressive considering that CoCoOp makes use of a meta-network and forward pass through the text encoder making it computationally intensive to train. CoCoOp takes up to 5 hours to train on 16-shot ImageNet for ViT-B/16 encoder, in comparison, our CLIP-A-self takes only 10 mins (on an RTX 3090 GPU). The Base-to-New generalization ability of our adapters is even more impressive for fine-grained, specialized datasets as evidenced by the gains over CoCoOp in Harmonic mean of base and new accuracy. For example, CLIP-A-self demonstrates gains in datasets like FGVC-Aircraft (7.5%), EuroSat (7.4%), DTD (5.8%), CUB (4.3%), Flowers102 (4%), Stanford Cars (2.4%) and UCF-101 (2.4%). This demonstrates that our adapters make use of semantic information in the form of visually descriptive sentences and fuse this with CLIP’s 0-shot knowledge to build more generalizable classifiers that transfer well to unseen classes within the same dataset. It is also worth noting that even though the same set of VDT did not provide any improvements in 0-shot domain transfer for datasets like FGVC-Aircraft, Stanford-Cars, and UCF-101, our self-attention adapter was able to choose the most informative subset of VDT and produce few-shot classifiers that provide substantial few-shot transfer performance gains in comparison to CoCoOp. We show in Section 4.5.1 the sentences picked by the attention mechanism for these datasets to qualitatively verify this.

### 4.5.1 Attention weights Analysis

We note that even though CLIP-GPT ensembles were out-performed by CLIP default prompt on FGVC Aircraft, UCF-101, and Stanford Cars dataset, we see that CLIP-A-self outperforms CLIP-A and CoCoOp [35] on these datasets in the few-shot transfer setting. We believe that this is because, during few-shot training, the self-attention mechanism learns to select the most relevant visual sentences out of the set of visually descriptive text and helps produce generalizable classifiers. In Table 1 in supplementary, we show the top 3 and bottom 3 attributes picked by attention scores for each of these datasets and show that the sentences with the highest attention scores correspond to visually descriptive attributes in the set and vice versa for the lowest scored attributes. For example, for both Stanford Cars and FGVC it is interesting to see that the color scheme is one of the least used attributes as it’s difficult to identify a car or a plane from its color or livery. For UCF-101, information like the force involved or temporal information like speed and range of motion of the action is unlikely to be encoded in the image and hence is not selected by the attention mechanism. Information regarding the subject and the object of the action, like the posture of the person, description of the object, and interaction between objects are visible in the images and hence weighted highly by the attention mechanism.

### 4.6. Ablation over different GPT models

In this section, we see if other GPT models like GPT-3.5 and the open-source model, OpenAssistant [14], are as capable as GPT-4 in generating visually descriptive information. We explore this on the CUB dataset as it is fine-grained and specialized. The results are presented in Table 6. We find that the performance improves with larger models which are more capable of memorizing accurate class information with less hallucination [33]. Even though we obtain decent performance with the open-source model OpenAssistant, the outputs were always inconsistent and noisy, resulting in a lot of clean-up effort in comparison to GPT-3.5 and GPT-4 where the outputs were in the form of concise sentences following a dictionary format. It is worth noting that our few-shot adapter is capable of picking out the best VDT information even from a noisy set, pushing the Base-to-New generalization performance of OpenAssistant, and GPT-3.5 close to that of GPT-4.

### 5. Conclusion

In this work, we show that using visually descriptive textual (VDT) information can improve the 0-shot domain transfer performance of CLIP over non-visual information and the default prompts. We demonstrate GPT-4 to be an accurate and flexible source of VDT information by improving the 0-shot domain transfer performances on a suite of 12 benchmark datasets. Our few-shot adapter CLIP-A-self learns to pick the best VDT information from the GPT generated set and improve the few-shot domain transfer in the Base-to-New setting even when the quality of the generated text deteriorates. We release all prompts and VDT information for all 12 datasets to promote further research in the fertile research direction of using LLMs for learning multi-modal adapters for foundation models.
