### Abstract

Recent emerged quantization technique (i.e., using low bit-width fixed-point data instead of high bit-width floating-point data) has been applied to inference of deep neural networks for fast and efficient execution. However, directly applying quantization in training can cause significant accuracy loss, thus remaining an open challenge. In this paper, we propose a novel training approach, which applies a layer-wise precision-adaptive quantization in deep neural networks. The new training approach leverages our key insight that the degradation of training accuracy is attributed to the dramatic change of data distribution. Therefore, by keeping the data distribution stable through a layer-wise precision-adaptive quantization, we are able to directly train deep neural networks using low bit-width fixed-point data and achieve guaranteed accuracy, without changing hyper parameters. Experimental results on a wide variety of network architectures (e.g., convolution and recurrent networks) and applications (e.g., image classification, object detection, segmentation and machine translation) show that the proposed approach can train these neural networks with negligible accuracy losses (-1.40%~1.3%, 0.02% on average), and speed up training by 252% on a state-of-the-art Intel CPU.

## 1. Introduction

While deep neural networks have become state-of-the-art techniques for a wide range of machine learning applications, such as image recognition [14], object detection [21], machine translation [32, 8], the computation costs of deep neural networks are continuously increasing, which greatly hampers the development and deployment of deep neural

\*Shaoli Liu is the corresponding author of this paper (Email: liushaoli@cambricon.com). This work was funded and supported by Cambricon Technologies.

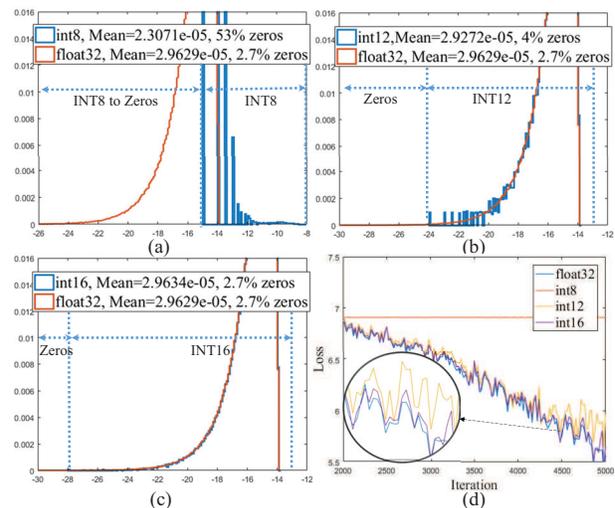

Figure 1: AlexNet fc2 layer activation gradient distribution (base-2 logarithm) and training convergence.

networks. For example, 10,000 GPU hours are used to perform neural architecture search on ImageNet [2]. Quantization is a promising technique to reduce the computation cost of neural network training, which can replace high-cost floating-point numbers (e.g., float32) with low-cost fixed-point numbers (e.g., int8/int16). Recently, both the software society [6, 12, 16, 19, 27, 35] and the hardware society [11, 24, 23, 31] have carried out extensive researches on quantization of deep neural network for inference tasks.

Though various investigations have demonstrated that deep learning inference can be accurately performed with low bit-width fixed-point numbers through quantization [16, 17, 6, 33, 35, 35, 37], the quantified training remains an open challenge. Some existing approaches quantify the backward-pass to low-bit (e.g., int8) but incur significant accuracy drop, for examples, 3~7% loss for AlexNet [38, 36]. [7] uses int16 for both forward-pass

and backward-pass to ensure accuracy. However, there is no guarantee that unified int16 precision works for all the tasks and networks. Compared to efficiency, accuracy is the primary pursuit in most practical training-from-scratch scenarios, so activation gradients in back propagation are still kept as float32 for most quantification work [16, 17, 6, 35, 39, 37]. Our aim is to study the correlation between training accuracy and calculation bit-width (efficiency) in back-propagation.

Most previous investigations on quantified training use unified precision (i.e., bit-width) for all network layers. Intuitively, using mixed precisions for different layers will promote the network performance. However, it is hard to find the most appropriate precisions for so many layers in so many training iterations. Considering a widely used ResNet50 model, with 4 candidate quantization bit-widths (e.g., 8, 16, 24, 32 for weights, activations and activation gradients), the size of quantization precision combination search space for 450,000 training iterations can achieve  $4^{3 \times 50 \times 450,000}$ .

To avoid prohibitively long space searching of quantization bit-width combinations, we propose an efficient and adaptive technique to determine the bit-width layer by layer separately, which is based on our observation about the relationship between the layer-wise bit-width and the training convergence. Take AlexNet as an example, Figure. 1(a-c) depicts the distributions of activation gradients on AlexNet last layer when quantified with different bit-widths. Compared with the original float32, int8 introduces a significant change in data distribution, int12 introduces slightly change of data mean, and int16 shows almost the same distribution with float32. Figure. 1(d) depicts the corresponding training loss, which shows int8 quantization does not converge at beginning, int12 converges slower than float32 and int16 behaves similar as float32. The above experimental results suggest if a quantization resolution does not change the data distribution of a layer (e.g., int16 for the last layer of AlexNet), quantified training with this resolution for the corresponding layer will almost keep the training accuracy.

Based on the above observation, one can train large-scale deep neural network using fixed-point numbers, with no change of hyper parameters and no accuracy degradation. For each layer in training, our approach automatically finds the best quantization resolution (i.e., the smallest bit-width which does not significantly change the data mean) for weights, activations and activation gradients respectively. Concretely, we first calculate the mean of the data before quantization. Then, we quantify the data using int8 and calculate the quantization error. If the ratio of quantization error exceeds a threshold (e.g., 3%), the quantization bit-width is increased. The above process is looped until the quantization error ratio is below the threshold.

We evaluate our approach on a wide variety of network

architectures (e.g. convolution and recurrent networks) and applications (e.g. image classification, object detection, segmentation and machine translation). Our approach quantifies all weights and activations to int8. On average, 12.56%, 87.43% and 0.07% of activation gradients are quantified to int8, int16, and int24 respectively. Experimental results show that the proposed adaptive fixed-point training approach can achieve comparable accuracy with float32 for training from scratch. The accuracy loss is only 0.02% on average (-1.40%~1.3%). Results on Intel Xeon Gold 6154 shows that the proposed approach can achieve 2.52 times speedup over float32 training for AlexNet.

We highlight three major contributions of the proposed adaptive fixed-point training:

1. **Flexibility:** The quantization precisions for different layers of different networks are automatically adapted to guarantee the network accuracy.
2. **Efficiency:** We quantify both the backward-pass and forward-pass with fixed-point numbers in training, which can accelerate training on real hardware. After training, int8 weights can be directly deployed, so no further quantification is needed.
3. **Generalization:** Evaluations on various networks and applications demonstrate the proposed adaptive fixed-point training is effective and practical.

## 2. Related Works

Using reduced precision for deep learning has been an active research topic. Prior efforts explore floating-points (e.g., 8-bit and 16-bit) for training [34, 22] and maintain accuracy on a spectrum of deep learning models and datasets. However, as floating-point is more resource-intensive than fixed-point, the deployments always rely on quantization techniques.

There are recent attempts quantifying weight and activation on different layers with different bit-widths. For the inference of a trained network, there are some techniques that heuristically search the space of quantization bit-width combinations [35, 33, 37]. However, these inference techniques only need to consider single iteration, whose search space is much smaller than training. Hence, they are unsuitable for training. For training, there are some differentiable quantization methods [4, 30, 37], introducing extra calculations to learn the quantization parameters (e.g., quantization resolution, range and bit-width) with gradient descent. However, the quantization parameters for backward propagation are hard to learn using differentiable methods. [26] quantifies the backward propagation. Different from their method, which assigns layer-wise bit-width before training, our approach dynamically changes the bit-width during training and we evaluate on widely used networks.

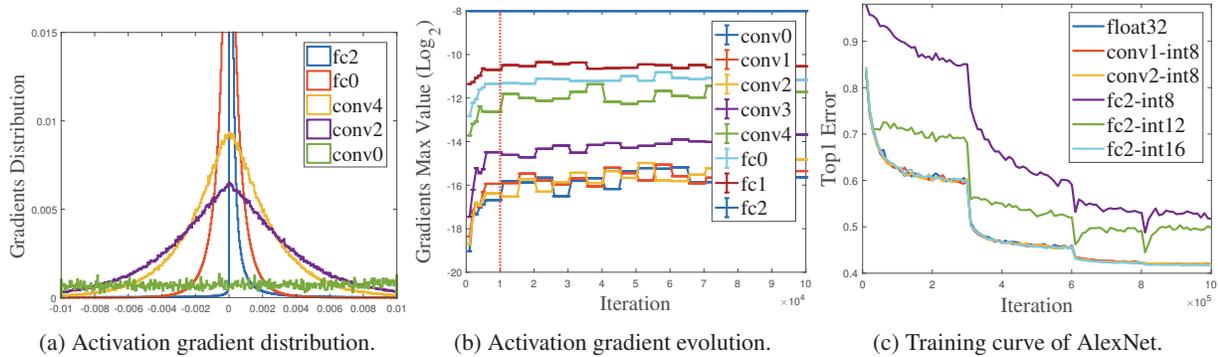

Figure 2: Observations on AlexNet.

Researchers have shown that 16-bit is sufficient for back propagation in most vision training tasks [7]. However, further quantization to 8-bit results in severe degradation [38, 38, 36, 7, 1]. WAGE [36] claims that first and last layers require higher precision. TBP [1] shows weight gradient computation (WTGRAD) needs more bits than gradient back propagation (BPROP).

Our approach is different from others in three aspects. First, fixed-point is used in both forward-pass and backward-pass for training. Second, the quantization parameters for different layers are dynamically adapted to guarantee the accuracy. Lastly, we train a variety of vision and natural language processing applications on large scale dataset.

### 3. Observation

The key of fixed-point training is to find proper quantization parameters that ensure the training accuracy. Therefore, we study the relationship between the ever-changing data distribution of different layers and the training convergence.

**Observation 1. Data distribution varies greatly between layers.** Figure. 2a depicts the distributions of activation gradients of different layers on AlexNet. The majority of activation gradients concentrate in areas close to zero, and have long tail distributions. Compared to convolution layers, the fully connected layers have larger variances. Figure. 2b shows the base-2 logarithm of max absolute value of activation gradients on AlexNet, the max value on bottom layers (e.g., conv0, conv1, conv2) is smaller than the max value on upper layers(e.g., fc0, fc1, fc2). Intuitively, for those layers whose range of data is wide and distribution is centralized, higher quantization resolutions are demanded.

**Observation 2. Data range of each layer changes during training.** Figure. 2b shows the max absolute value of activation gradient evolution during training. At the early stage of training (less than 10,000 iterations, as shown on the left side of the red line), the data range changes rapidly,

and after one or two epochs, the data range tends to be stable. This phenomenon suggests that when training from scratch, the quantization range should also be changed frequently within the initial epochs .

**Observation 3. Data with large variance requires large bit-width.** Figure. 2c shows the convergence curves using different bit-width of different layers. Float32 is the training convergence curve of using float32 for all the convolution and fully connected layers. After 5,000,000 iterations, the network’s top1 accuracy on ImageNet is 58.00%. Then, we quantify the activation gradients of conv1 to int8 and keep other layers float32. The training curve of conv1-int8 is the same as float32 and the final top1 accuracy is 58.01%. However, when we quantify the activation gradients of fc2 to int8 and keep other layers float32 unchanged, the training convergence speed is significantly slower than float32, and within the first 5,000 iterations the training does not converge. The final top1 accuracy of fc2-int8 is only 48.27%. When quantifying the activation gradients of fc2 to int12, the training convergence speed is faster than int8 but still slower than float32. The final top1 accuracy of fc2-int12 is only 50.30%. Using int16 for the activation gradients of fc2, finally the training curve is the same as float32 with 58.28% top1 accuracy. In conclusion, int8 is enough to quantify the activation gradient of conv2, however, fc2 requires int16 to maintain the training accuracy. Together with the observation1, we find that data with large variance requires large bit-width, thus the quantization parameters should be dynamically determined by the data distribution.

According to network initialization principle [10, 13], all network parameters are initialized as Gaussian distribution with variance relating to the hyper-parameters of layers. Similar network initialization principle and similar SGD learning algorithm ensure that various network architectures should have similar observations.(More observations are in Appendix C.)

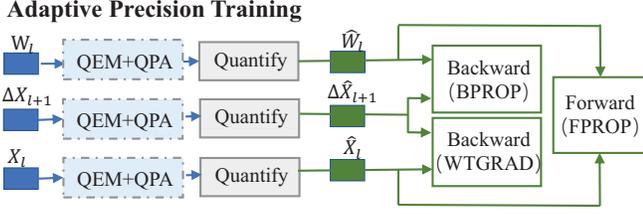

Figure 3: Adaptive fixed-point training for one iteration one layer. The green nodes and blocks indicate fixed-point data and calculations. Only 0.01%~2% of the iterations activate the QEM and QPA components.

## 4. Adaptive Fixed-Point Training

In this section, we introduce the adaptive fixed-point training approach as shown in Figure. 3. In training, the main three computing units of single iteration include forward-pass (FPROP), backward-pass for gradient propagation (BPROP) and backward-pass for weight gradient computation (WTGRAD). The inputs of these three units include weight  $W_l$ , activation  $X_l$  and top layers' activation gradient  $\Delta X_{l+1}$  of linear layer  $l$ . In adaptive fixed-point training, we quantify these three inputs to fixed-point numbers<sup>1</sup>. The quantification parameters, such as bit-width  $n$  and quantization resolution  $r$  are automatically determined by the proposed Quantization Error Measurement (QEM) and Quantification Parameter Adjustment (QPA).

In the following part of this section, we will introduce two main components QEM and QPA of our training approach. Algorithm. 1 describes the entire adaptive fixed-point training algorithm. The output of QEM (denoted as  $Diff$ ) serves as an explicit indicator for insufficiency of quantization resolution according to data distribution. QPA performs quantization parameter update and determines update frequency (denoted as  $Itv$ ) according to the output of QEM.

### 4.1. Quantization Error Measurement

Based on the observation 1 and observation 3, we propose to adjust quantization parameters according to data distribution. The difference of mean before and after quantization is a good quantization error measurement, which indicates the change of data distribution and suggests the need for adjusting quantization resolution.

Intuitively, as shown in Figure. 4, the orange line and blue line represent two different data distributions. The quantization resolution is shown as the distance between  $a$  and  $b$ , and the data in between is quantified to  $a$ . Using certain quantization parameters (reflected by quantization resolution in figure), the distribution difference can be reflected by the difference of shadow areas. Specifically,

<sup>1</sup>The quantification method is described in Appendix B

---

**Algorithm 1** Adaptive fixed-point training. Data such as weights  $W_l$ , activations  $X_l$  and top layers' activation gradients  $\Delta X_{l+1}$  of the linear layer  $l$  are quantified to fixed-point numbers with different bit-widths  $n$  and quantization resolution  $r$ . The output  $Diff$  of QEM indicates the insufficiency of quantization resolution, and the output  $Itv$  of QPA determines quantization parameter update frequency.

    Backward:  $\Delta X_l = \Delta \hat{X}_{l+1} * \hat{W}_l^T // BPROP$ 
    Backward:  $\Delta W_l = \hat{X}_l^T * \Delta \hat{X}_{l+1} // WTGRAD$ 
  //Weight Update
   $W_l = W_l + f(\Delta W_l)$ 
  end while
end while

```

---

the shadow area S1 is approximately equal to S2 for orange distribution, but S3 is much larger than S4 for blue distribution, which means far more amount of data is quantified to  $a$  under the blue distribution. Therefore, for blue one, the mean value after quantization  $m_d$  is much smaller than the original mean value  $m_d$ . As the distance between  $a$  and  $b$  reduces, the area difference between S3 and S4 will also be reduced. Therefore, the difference of mean value before and after quantization reflects the connection between quantization resolution and data distribution.

Mathematically, assuming that the data is under Gaussian distribution  $P(x) \sim G(0, \sigma)$ , and data  $x \in R^p$  is quantified to  $\hat{x}$ . Considering the positive  $x$ , the mean between  $[a, b]$  is  $m_x = \frac{\int_a^b P(x)xdx}{\int_a^b P(x)dx}$ , and after quantification the

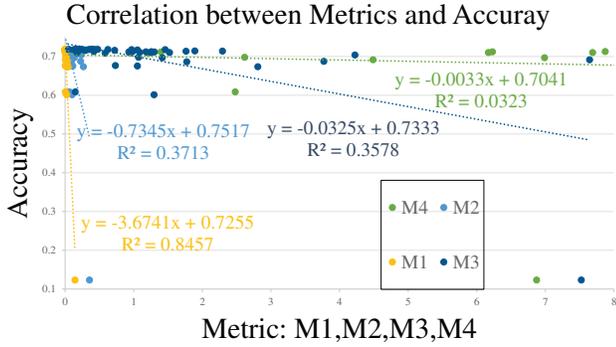

Figure 5: Correlation between MobileNet-v2 accuracy  $a$  and quantization error measurement  $M$ .

$\sum_i \frac{|x_i - \hat{x}_i|}{|x_i|}$ ,  $M3 = \sum_i \frac{|x_i - \hat{x}_i|}{|x_i|}$ ,  $M4 = \sum_j P_j \log(\frac{P_j}{Q_j})$ . M2 is similar as in [27, 39]. M4 is the Kullback-Leibler divergence, with  $P_j$  and  $Q_j$  are the discrete probability distributions of original data and data after quantization. Specifically, we quantify each single layer of MobileNet-v2 and do the forward propagation to get the corresponding network accuracy. The quantization is done with different bit-width (i.e., 6, 8), so various degrees of quantization error and the corresponding network accuracy are generated.

Figure. 5 shows the linear correlation between network accuracy and several error metrics. Our proposed quantization error measurement M1 has the highest correlation score (0.84 for MobileNet and 0.85 for ResNet50 in Appendix D) with the network-level accuracy, which means the proposed error measurement can serve as a reasonable layer-wise accuracy indicator. MobileNet, as light-weight network, is relatively hard to quantified, so it can exhibit the most noticeable difference between different evaluation metrics M1, M2, M3 and M4.

## 5.2. Computational Complexity

We evaluate the extra computations introduced by adaptive fixed-point quantization. The extra computations refer to calculations in QEM, QPA and data quantification, denoted as **forward quantification** and **backward quantification** in Figure. 6 and Figure. 7. These two figures show the operation percentages and running time for different networks<sup>2</sup>. For light-weight network MobileNet, the extra computation is relatively large. For other networks, the extra computation is within 1%. The speed of our method is 1.7x to 2.8x of float32 speed on GPU.

During training, the adjustment frequency is calculated as  $\frac{Adj\_Iter}{Iter}$ , where  $Adj\_Iter$  is the number of iteration that performs QEM and QPA, and  $Iter$  is the total number of executed training iterations. As shown in Figure. 8a, at the initial epochs, the adjustment frequency is near 100%. As

<sup>2</sup><https://github.com/tensorflow/models/tree/master/research/slim>

the training progresses, the adjustment frequency is dramatically decreasing to 0.1% at end.

Figure. 8b shows the percentage of activation gradients quantified to int8 during training on VGG16. Mode1 allows the bit-width both to increase and to decrease in the training, while Mode2 only allows the bit-width to increase. In Mode1, on average 39.6% layers are kept int8 (final top1 accuracy: 70.2%). In Mode2, on average 18.8% of layers are kept int8 (final top1 accuracy: 70.6%).

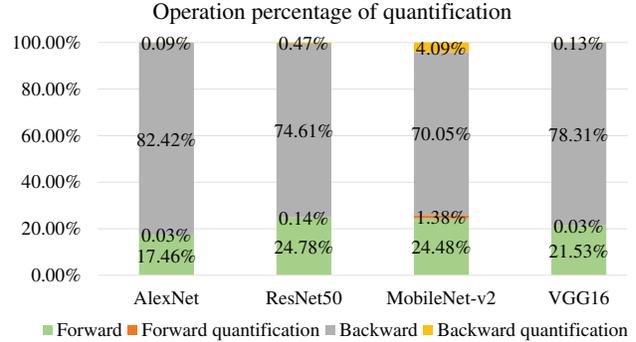

Figure 6: Operation percentage of forward and backward quantification for different models.

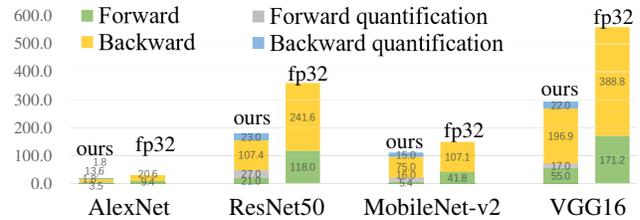

Figure 7: Time (ms) for one iteration on V100 GPU with 128 batchsize. As V100 does not support int16, here float16 is used to approximate int16.

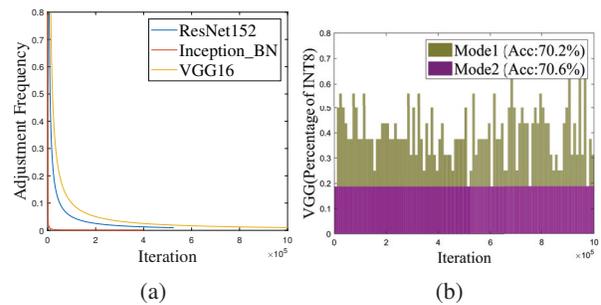

Figure 8: (a) Quantification parameter adjustment frequency during training. (b) Int8 percentage during training.

Table 1: Classification, object detection and segmentation. For all the networks, 100% weights and 100% activations are quantified to int8.

Classification Network	float32 Acc	Adaptive Acc	Activation Gradient int8	Gradient int16
AlexNet	58.0	58.22	22.5%	77.5%
VGG16	71.0	70.6	31.3%	68.7%

### 5.3. Accuracy Results

Our proposed Adaptive Fixed-Point Training approach uses **all the same** hyper-parameters (e.g., learning rate, max training iterations and *etc.*) as the original float32 training settings. For all the tasks, we fix the initial bit-width to int8<sup>3</sup>, with  $\alpha = 0.04$ ,  $\beta = 0.1$ ,  $\delta = 100$ ,  $\gamma = 2$ ,  $T_{data} = 0.03$ , and Mode2 is used in QPA.

#### 5.3.1 Computer Vision

We train several convolution neural networks with ImageNet datasets using Tensorflow framework<sup>4</sup>. The networks include AlexNet [18], VGG [28], Inception\_BN [29], ResNet [14] and MobileNet v2 [27]<sup>5</sup>. We train SSD object detection networks [21]<sup>6</sup> with VOC dataset [9], COCO dataset [20] and Imagnet Detection dataset (IMG) [25] upon two backbone networks VGG and ResNet101. We train deeplab [3]<sup>7</sup> segmentation network on VOC dataset. For classification task, Top1 Accuracy (Acc) is used as evaluation metric. For object detection task, Mean Average Precision (mAP) is used as evaluation metric. For segmentation task, Mean Intersection over Union (meanIoU) is used as evaluation metric.

As shown in Table. 1, Adaptive Fixed-Point Training generates similar results as float32 baseline. The accuracy drop on MobileNet-v2 is consistent with the quantization results in Google’s work (Acc:70.8) [16]. However, using

<sup>3</sup>Appendix E shows results of adaptive lower bit-width (i.e., int4) for these forward-pass.

<sup>4</sup><https://github.com/tensorpack/tensorpack/tree/master/examples/>

<sup>5</sup><https://github.com/tensorflow/models/tree/master/research/slim>

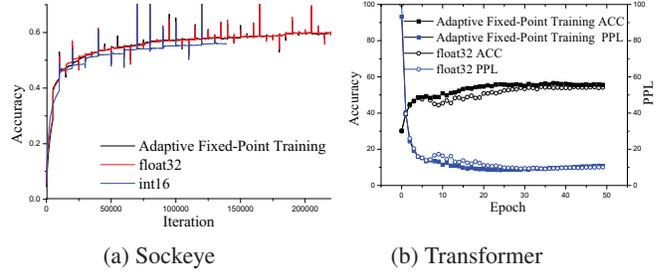

Figure 9: Machine translation.

our adaptive precision fixed-point training, int8 weights can be directly deployed and no further quantified fine-tuning is needed. The proposed QEM and QPA automatically change the bit-width used for different layers. During the whole training, the percentages of different bit-width in quantization are shown in Table. 1<sup>8</sup>. For backward activation gradient, int16 is needed for most layers and networks, but for some layers of AlexNet and SSD, int8 is enough.

The use of same hyper-parameters in training indicates that Adaptive Fixed-Point Training has the same convergence speed as float32 training. (More loss curves are shown in Appendix F.)

#### 5.3.2 Machine Translation

We train two widely used machine translation models from scratch with Adam optimizer. The first Sockeye [15] is a sequence-to-sequence RNN model implemented with MXNet [5]<sup>9</sup>, and trained on the WMT’17 news translation dataset (50k sentence pairs). The word vocabularies contain 50K entries for English and German. The second is Transformer [32]<sup>10</sup>, utilizing self-attention mechanism. This network is trained on the WMT’16 Multi30k dataset (3.9k sentence pairs). Word-level accuracy and perplexity (PPL) are used as evaluation metrics.

Training curve of Sockeye is shown in Figure. 9a. Adaptive Fixed-Point Training is compared with float32 baseline and an int16 method, which employs int16 to quantified all the layers of activation gradients without bit-width adaption. At the end of Adaptive Fixed-Point Training, 0.8% layers of activation gradients are quantified to int24, 10% layers are int8, and others are int16. As shown in Figure. 9a, the int16 method gradually results in 2% loss of accuracy, while our Adaptive Fixed-Point generates the same accuracy (62.05%) as float 32 baseline (61.97%). This comparison shows the proposed bit-width adaption is necessary to

<sup>8</sup>This is the results of Mode2, as Mode2 generates slightly better results than Mode1, as shown in Figure. 8(b).

<sup>9</sup><https://github.com/aws-labs/sockeye>

guarantee training accuracy and reduces the total bit-width in computation.

The training convergence curve of Transformer is shown in Figure. 9b. We report the accuracy and PPL on validation set. Adaptive Fixed-Point (Acc: 55.54%) is slightly better than float32 (Acc: 54.13%). On average 2.28% of iterations trigger quantization parameter adjustment.

### 5.3.3 Comparison to Others

Table. 2 shows the comparison to other quantization work. We estimate the speeds of previous methods with a simple rule widely used in [38, 7]: Int16/float16 and int8/float8 operations are 2x and 4x faster than float32 operations respectively. Fig.10 compares the speeds and accuracies of quantization methods with low bit-width back propagation [34, 22, 38, 36, 1, 7]. It shows that our method remarkably outperforms the pareto front of previous methods. Regarding accuracy, our method has the best accuracy among all quantization methods, and is the only method having similar accuracies with float32 across all networks; regarding speed, our method is at least 21% faster than the most accurate quantization method [7](whose VGG16 accuracy is lower than ours for > 2%).

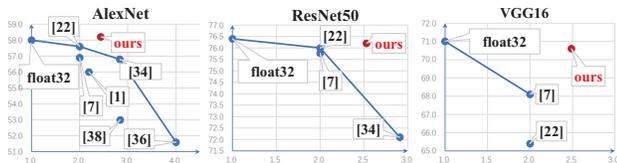

Figure 10: Accuracy (vertical axis) and estimated speed ratio against float32 (horizontal axis) on ImageNet.

Table 3: Layer-wise training speedup of AlexNet

	conv0	conv1	conv2	conv3	conv4
CPU Forward	2.03	3.89	6.2	4.44	4.28
CPU Backward	1.91	1.71	1.78	2.21	2.07
	fc0	fc1	fc2	Overall	
CPU Forward	4.09	6.42	4.41	3.98	
CPU Backward	4.41	4.97	2.03	2.07	

## 6. Training Acceleration

Intel Xeon Gold 6154 supports vector int8/int16 operations with AXV2 instruction set. Table. 3 shows the speedup of our method compared with float32 in training. Specifically, we use 100 iterations’ average acceleration ratio of each layer in forward-pass and backward-pass for AlexNet with 256 batch size<sup>11</sup>. Our approach can achieve 2.52 times speedup over float32 training on CPU.

## 7. Conclusion and Future Work

With the novel training scheme presented in this paper, AI processors no longer need to equip expensive floating-point hardware units to support deep learning training tasks. Instead, lightweight fixed-point hardware units, which consumes much smaller chip area and power, have been sufficient for training. Therefore, given the same budget of chip area/power, training performance of an AI processor could be made much higher than before, which is definitely a good news for chip designers and users. Recent chip products of Cambricon, including MLU220, MLU270 and the upcoming MLU290, can efficiently support the adaptive fixed-point training scheme proposed in this paper.

<sup>11</sup>Xeon Gold 6154 can only support multiplication between equal bit-width fixed-point numbers, so in this experiment int16 × int8 is implemented as int16 × int16.
